Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers may always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

EDITORS IN CHIEF

Shoba Ranganathan holds a Chair in Bioinformatics at Macquarie University since 2004. She has held research and academic positions in India, USA, Singapore and Australia as well as a consultancy in industry. She hosted the Macquarie Node of the ARC Centre of Excellence in Bioinformatics (2008–2013). She was elected the first Australian Board Director of the International Society for Computational Biology (ISCB; 2003–2005); President of Asia-Pacific Bioinformatics Network (2005–2016) and Steering Committee Member (2007–2012) of Bioinformatics Australia. She initiated the Workshops on Education in Bioinformatics (WEB) as an ISMB2001 Special Interest Group meeting and also served as Chair of ICSB's Education Committee. Shoba currently serves as Co-Chair of the Computational Mass Spectrometry (CompMS) initiative of the Human Proteome Organization (HuPO), ISCB and Metabolomics Society and as Board Director, APBioNet Ltd.

Shoba's research addresses several key areas of bioinformatics to understand biological systems using computational approaches. Her group has achieved both experience and expertise in different aspects of computational biology, ranging from metabolites and small molecules to biochemical networks, pathway analysis and computational systems biology. She has authored as well as edited several books as well as articles for the 2013 Encyclopedia of Systems Biology. She is currently an Editor-in-Chief of the Encyclopedia of Bioinformatics and

Computational Biology and the Bioinformatics Section Editor of the Reference Module in Life Science as well as an editorial board member of several bioinformatics journals.

Dr. Gribskov graduated from Oregon State University in 1979 with a Bachelors of Science degree (with Honors) in Biochemistry and Biophysics. He then moved to the University of Wisconsin-Madison for graduate studies focused on the structure and function of the sigma subunit of *E. coli* RNA polymerase, receiving his Ph.D. in 1985. Dr. Gribskov studied X-ray crystallography as an American Cancer Society post-doctoral fellow at UCLA in the laboratory of David Eisenberg, and followed this with both crystallographic and computational studies at the National Cancer Institute. In 1992, Dr. Gribskov moved to the San Diego Supercomputer Center at the University of California, San Diego where he was lead scientist in the area of computational biology and an adjunct associate professor in the department of Biology. From 2003 to 2007, Dr. Gribskov was the president of the International Society for Computational Biology, the largest professional society devoted to bioinformatics and computational biology. In 2004, Dr. Gribskov moved to Purdue University where he holds an appointment as a full professor in the Biological Sciences and Computer Science departments (by courtesy). Dr. Gribskov's interests include genomic and transcriptomic analysis of model and non-model

organisms, the application of pattern recognition and machine learning techniques to biomolecules, the design and implementation of biological databases to support molecular and systems biology, development of methods to study RNA structural patterns, and systems biology studies of human disease.

Kenta Nakai received the PhD degree on the prediction of subcellular localization sites of proteins from Kyoto University in 1992. From 1989, he has worked at Kyoto University, National Institute of Basic Biology, and Osaka University. From 1999 to 2003, he was an Associate Professor at the Human Genome Center, the Institute of Medical Science, the University of Tokyo, Japan. Since 2003, he has been a full Professor at the same institute. His main research interest is to develop computational ways for interpreting biological information, especially that of transcriptional regulation, from genome sequence data. He has published more than 150 papers, some of which have been cited more than 1,000 times.

Christian Schönbach is currently Department Chair and Professor at Department of Biology, School of Science and Technology, Nazarbayev University, Kazakhstan and Visiting Professor at International Research Center for Medical Sciences at Kumamoto University, Japan. He is a bioinformatics practitioner interfacing genetics, immunology and informatics conducting research on major histocompatibility complex, immune responses following virus infection, biomedical knowledge discovery, peroxisomal diseases, and autism spectrum disorder that resulted in more than 80 publications. His previous academic appointments included Professor at Kumamoto University (2016–2017), Nazarbayev University (2013–2016), Kazakhstan, Kyushu Institute of Technology (2009–2013) Japan, Associate Professor at Nanyang Technological University (2006–2009), Singapore, and Team Leader at RIKEN Genomic Sciences Center (2002–2006), Japan. Other prior positions included Principal Investigator at Kent Ridge Digital Labs, Singapore and Research Scientist at Chugai Institute for Molecular Medicine, Inc., Japan. In 2018 he became a member of International Society for Computational Biology (ISCB) Board of Directors. Since 2010 he is serving Asia-Pacific Bioinformatics Network (APBioNet) as Vice-President (Conferences 2010–2016) and President (2016–2018).

VOLUME EDITORS

Mario Cannataro is a Full Professor of Computer Engineering and Bioinformatics at University “Magna Graecia” of Catanzaro, Italy. He is the director of the Data Analytics research center and the chair of the Bioinformatics Laboratory at University “Magna Graecia” of Catanzaro. His current research interests include bioinformatics, medical informatics, data analytics, parallel and distributed computing. He is a Member of the editorial boards of Briefings in Bioinformatics, High-Throughput, Encyclopedia of Bioinformatics and Computational Biology, Encyclopedia of Systems Biology. He was guest editor of several special issues on bioinformatics and he is serving as a program committee member of several conferences. He published three books and more than 200 papers in international journals and conference proceedings. Prof. Cannataro is a Senior Member of IEEE, ACM and BITS, and a member of the Board of Directors for ACM SIGBIO.

Bruno Gaeta is Senior Lecturer and Director of Studies in Bioinformatics in the School of Computer Science and Engineering at UNSW Australia. His research interests cover multiple areas of bioinformatics including gene regulation and protein structure, currently with a focus on the immune system, antibody genes and the generation of antibody diversity. He is a pioneer of bioinformatics education and has trained thousands of biologists and trainee bioinformaticians in the use of computational tools for biological research through courses, workshops as well as a book series. He has worked both in academia and in the bioinformatics industry, and currently coordinates the largest bioinformatics undergraduate program in Australia.

Mohammad Asif Khan, PhD, is an associate professor and the Dean of the School of Data Sciences, as well as the Director of the Centre for Bioinformatics at Perdana University, Malaysia. He is also a visiting scientist at the Department of Pharmacology and Molecular Sciences, Johns Hopkins University School of Medicine (JHUSOM), USA. His research interests are in the area of biological data warehousing and applications of bioinformatics to the study of immune responses, vaccines, inhibitory drugs, venom toxins, and disease biomarkers. He has published in these areas, been involved in the development of several novel bioinformatics methodologies, tools, and specialized databases, and currently has three patent applications granted. He has also led the curriculum development of a Postgraduate Diploma in Bioinformatics programme and an MSc (Bioinformatics) programme at Perdana University. He is an elected ExCo member of the Asia-Pacific Bioinformatics Network (APBioNET) since 2010 and is currently the President of Association for Medical and Bio-Informatics, Singapore (AMBIS). He has donned various important roles in the organization of many local and international bioinformatics conferences, meetings and workshops.

CONTENTS OF VOLUME 1

Editors in Chief	v
Volume Editors	vii
List of Contributors for Volume 1	xvii
Preface	xxi

VOLUME 1

Algorithms Foundations <i>Nadia Pisanti</i>	1
Techniques for Designing Bioinformatics Algorithms <i>Massimo Cafaro, Italo Epicoco, and Marco Pulimeno</i>	5
Algorithms for Strings and Sequences: Searching Motifs <i>Francesco Cauteruccio, Giorgio Terracina, and Domenico Ursino</i>	15
Algorithms for Strings and Sequences: Pairwise Alignment <i>Stefano Beretta</i>	22
Algorithms for Strings and Sequences: Multiple Alignment <i>Pietro H Guzzi</i>	30
Algorithms for Structure Comparison and Analysis: Prediction of Tertiary Structures of Proteins <i>Giuseppe Tradigo, Francesca Rondinelli, and Gianluca Pollastri</i>	32
Algorithms for Structure Comparison and Analysis: Homology Modelling of Proteins <i>Marco Wiltgen</i>	38
<i>Ab initio</i> Protein Structure Prediction <i>Rahul Kaushik, Ankita Singh, and B Jayaram</i>	62
Algorithms for Structure Comparison and Analysis: Docking <i>Giuseppe Tradigo, Francesca Rondinelli, and Gianluca Pollastri</i>	77
Algorithms for Graph and Network Analysis: Graph Indexes/Descriptors <i>Lo Giudice Paolo and Domenico Ursino</i>	81
Algorithms for Graph and Network Analysis: Traversing/Searching/Sampling Graphs <i>Paolo Lo Giudice and Domenico Ursino</i>	89
Algorithms for Graph and Network Analysis: Clustering and Search of Motifs in Graphs <i>Clara Pizzuti and Simona E Rombo</i>	95
Algorithms for Graph and Network Analysis: Graph Alignment <i>Luigi Palopoli and Simona E Rombo</i>	102
Bioinformatics Data Models, Representation and Storage <i>Mariaconcetta Bilotta, Giuseppe Tradigo, and Pierangelo Veltri</i>	110
Data Storage and Representation <i>Antonella Guzzo</i>	117
Experimental Platforms for Extracting Biological Data: Mass Spectrometry, Microarray, Next Generation Sequencing <i>Barbara Calabrese</i>	126

Standards and Models for Biological Data: Common Formats <i>Barbara Calabrese</i>	130
Standards and Models for Biological Data: FGED and HUPO <i>Barbara Calabrese</i>	137
Standards and Models for Biological Data: SBML <i>Giuseppe Agapito</i>	142
Standards and Models for Biological Data: BioPAX <i>Giuseppe Agapito</i>	147
Models for Computable Phenotyping <i>Alfredo Tirado-Ramos and Laura Manuel</i>	154
Computing for Bioinformatics <i>Mario Cannataro and Giuseppe Agapito</i>	160
Computing Languages for Bioinformatics: Perl <i>Giuseppe Agapito</i>	176
Computing Languages for Bioinformatics: BioPerl <i>Giuseppe Agapito</i>	187
Computing Languages for Bioinformatics: Python <i>Pietro H Guzzi</i>	195
Computing Languages for Bioinformatics: R <i>Marianna Milano</i>	199
Computing Languages for Bioinformatics: Java <i>Pietro H Guzzi</i>	206
Parallel Architectures for Bioinformatics <i>Ivan Merelli</i>	209
Models and Languages for High-Performance Computing <i>Domenico Talia</i>	215
MapReduce in Computational Biology Via Hadoop and Spark <i>Giuseppe Cattaneo, Raffaele Giancarlo, Umberto Ferraro Petrillo, and Gianluca Roscigno</i>	221
Infrastructure for High-Performance Computing: Grids and Grid Computing <i>Ivan Merelli</i>	230
Infrastructures for High-Performance Computing: Cloud Computing <i>Paolo Trunfio</i>	236
Infrastructures for High-Performance Computing: Cloud Infrastructures <i>Fabrizio Marozzo</i>	240
Infrastructures for High-Performance Computing: Cloud Computing Development Environments <i>Fabrizio Marozzo and Paolo Trunfio</i>	247
Cloud-Based Bioinformatics Tools <i>Barbara Calabrese</i>	252
Cloud-Based Bioinformatics Platforms <i>Barbara Calabrese</i>	257
Cloud-Based Molecular Modeling Systems <i>Barbara Calabrese</i>	261
The Challenge of Privacy in the Cloud <i>Francesco Buccafurri, Vincenzo De Angelis, Gianluca Lax, Serena Nicolazzo, and Antonino Nocera</i>	265

Artificial Intelligence and Machine Learning in Bioinformatics <i>Kaitao Lai, Natalie Twine, Aidan O'Brien, Yi Guo, and Denis Bauer</i>	272
Artificial Intelligence <i>Francesco Scardcello</i>	287
Knowledge and Reasoning <i>Francesco Ricca and Giorgio Terracina</i>	294
Machine Learning in Bioinformatics <i>Jyotsna T Wassan, Haiying Wang, and Huiru Zheng</i>	300
Intelligent Agents and Environment <i>Alfredo Garro, Max Mühlhäuser, Andrea Tundis, Stefano Mariani, Andrea Omicini, and Giuseppe Vizzari</i>	309
Intelligent Agents: Multi-Agent Systems <i>Alfredo Garro, Max Mühlhäuser, Andrea Tundis, Matteo Baldoni, Cristina Baroglio, Federico Bergenti, and Paolo Torroni</i>	315
Stochastic Methods for Global Optimization and Problem Solving <i>Giovanni Stracquadanio and Panos M Pardalos</i>	321
Data Mining in Bioinformatics <i>Chiara Zucco</i>	328
Knowledge Discovery in Databases <i>Massimo Guarascio, Giuseppe Manco, and Ettore Ritacco</i>	336
Supervised Learning: Classification <i>Mauro Castelli, Leonardo Vanneschi, and Álvaro Rubio Largo</i>	342
Unsupervised Learning: Clustering <i>Angela Serra and Roberto Tagliaferri</i>	350
Data Mining: Mining Frequent Patterns, Associations Rules, and Correlations <i>Massimo Cafaro, Italo Epicoco, and Marco Pulimeno</i>	358
Association Rules and Frequent Patterns <i>Giuseppe Di Fatta</i>	367
Decision Trees and Random Forests <i>Michele Fratello and Roberto Tagliaferri</i>	374
Data Mining: Classification and Prediction <i>Alfonso Urso, Antonino Fiannaca, Massimo La Rosa, Valentina Ravì, and Riccardo Rizzo</i>	384
Bayes' Theorem and Naive Bayes Classifier <i>Daniel Berrar</i>	403
Data Mining: Prediction Methods <i>Alfonso Urso, Antonino Fiannaca, Massimo La Rosa, Valentina Ravì, and Riccardo Rizzo</i>	413
Data Mining: Accuracy and Error Measures for Classification and Prediction <i>Paola Galdi and Roberto Tagliaferri</i>	431
Data Mining: Clustering <i>Alessia Amelio and Andrea Tagarelli</i>	437
Computation Cluster Validation in the Big Data Era <i>Raffaele Giancarlo and Filippo Utró</i>	449
Data Mining: Outlier Detection <i>Fabrizio Angiulli</i>	456

Pre-Processing: A Data Preparation Step <i>Swarup Roy, Pooja Sharma, Keshab Nath, Dhruba K Bhattacharyya, and Jugal K Kalita</i>	463
Data Cleaning <i>Barbara Calabrese</i>	472
Data Integration and Transformation <i>Barbara Calabrese</i>	477
Data Reduction <i>Barbara Calabrese</i>	480
Dimensionality Reduction <i>Italia De Feis</i>	486
Kernel Machines: Introduction <i>Italo Zoppis, Giancarlo Mauri, and Riccardo Dondi</i>	495
Kernel Methods: Support Vector Machines <i>Italo Zoppis, Giancarlo Mauri, and Riccardo Dondi</i>	503
Kernel Machines: Applications <i>Italo Zoppis, Giancarlo Mauri, and Riccardo Dondi</i>	511
Multiple Learners Combination: Introduction <i>Chiara Zucco</i>	519
Multiple Learners Combination: Bagging <i>Chiara Zucco</i>	525
Multiple Learners Combination: Boosting <i>Chiara Zucco</i>	531
Multiple Learners Combination: Stacking <i>Chiara Zucco</i>	536
Multiple Learners Combination: Cascading <i>Chiara Zucco</i>	539
Cross-Validation <i>Daniel Berrar</i>	542
Performance Measures for Binary Classification <i>Daniel Berrar</i>	546
Natural Language Processing Approaches in Bioinformatics <i>Xu Han and Chee K Kwoh</i>	561
Text Mining Basics in Bioinformatics <i>Carmen De Maio, Giuseppe Fenza, Vincenzo Loia, and Mimmo Parente</i>	575
Data-Information-Concept Continuum From a Text Mining Perspective <i>Danilo Cavaliere, Sabrina Senatore, and Vincenzo Loia</i>	586
Text Mining for Bioinformatics Using Biomedical Literature <i>Andre Lamurias and Francisco M Couto</i>	602
Multilayer Perceptrons <i>Leonardo Vanneschi and Mauro Castelli</i>	612
Delta Rule and Backpropagation <i>Leonardo Vanneschi and Mauro Castelli</i>	621
Deep Learning <i>Massimo Guarascio, Giuseppe Manco, and Ettore Ritacco</i>	634

Introduction to Biostatistics <i>Antonella Iuliano and Monica Franzese</i>	648
Descriptive Statistics <i>Monica Franzese and Antonella Iuliano</i>	672
Measurements of Accuracy in Biostatistics <i>Haiying Wang, Jyotsna T Wassan, and Huiru Zheng</i>	685
Hypothesis Testing <i>Claudia Angelini</i>	691
Statistical Inference Techniques <i>Daniela De Canditiis</i>	698
Correlation Analysis <i>Monica Franzese and Antonella Iuliano</i>	706
Regression Analysis <i>Claudia Angelini</i>	722
Nonlinear Regression Models <i>Audrone Jakaitiene</i>	731
Parametric and Multivariate Methods <i>Luisa Cutillo</i>	738
Stochastic Processes <i>Maria Francesca Carfora</i>	747
Hidden Markov Models <i>Monica Franzese and Antonella Iuliano</i>	753
Linkage Disequilibrium <i>Barbara Calabrese</i>	763
Introduction to the Non-Parametric Bootstrap <i>Daniel Berrar</i>	766
Population-Based Sampling and Fragment-Based <i>De Novo</i> Protein Structure Prediction <i>David Simoncini and Kam YJ Zhang</i>	774
Ontology: Introduction <i>Gianluigi Greco, Marco Manna, and Francesco Ricca</i>	785
Ontology: Definition Languages <i>Valeria Fionda and Giuseppe Pirrò</i>	790
Ontology: Querying Languages and Development <i>Valeria Fionda and Giuseppe Pirrò</i>	800
Ontology in Bioinformatics <i>Pietro Hiram Guzzi</i>	809
Biological and Medical Ontologies: Introduction <i>Marco Masseroli</i>	813
Biological and Medical Ontologies: GO and GOA <i>Marco Masseroli</i>	823
Biological and Medical Ontologies: Protein Ontology (PRO) <i>Davide Chicco and Marco Masseroli</i>	832
Biological and Medical Ontologies: Disease Ontology (DO) <i>Anna Bernasconi and Marco Masseroli</i>	838

Biological and Medical Ontologies: Human Phenotype Ontology (HPO) <i>Anna Bernasconi and Marco Masseroli</i>	848
Biological and Medical Ontologies: Systems Biology Ontology (SBO) <i>Anna Bernasconi and Marco Masseroli</i>	858
Ontology-Based Annotation Methods <i>Pietro H Guzzi</i>	867
Semantic Similarity Definition <i>Francisco M Couto and Andre Lamurias</i>	870
Semantic Similarity Functions and Measures <i>Giuseppe Pirrò</i>	877
Tools for Semantic Analysis Based on Semantic Similarity <i>Marianna Milano</i>	889
Functional Enrichment Analysis Methods <i>Pietro H Guzzi</i>	896
Gene Prioritization Using Semantic Similarity <i>Erinija Pranckeviciene</i>	898
Gene Prioritization Tools <i>Marianna Milano</i>	907
Networks in Biology <i>Valeria Fionda</i>	915
Graph Theory and Definitions <i>Stefano Beretta, Luca Denti, and Marco Previtali</i>	922
Network Properties <i>Stefano Beretta, Luca Denti, and Marco Previtali</i>	928
Graph Isomorphism <i>Riccardo Dondi, Giancarlo Mauri, and Italo Zoppis</i>	933
Graph Algorithms <i>Riccardo Dondi, Giancarlo Mauri, and Italo Zoppis</i>	940
Network Centralities and Node Ranking <i>Raffaele Giancarlo, Daniele Greco, Francesco Landolina, and Simona E Rombo</i>	950
Network Topology <i>Giuseppe Manco, Ettore Ritacco, and Massimo Guarascio</i>	958
Network Models <i>Massimo Guarascio, Giuseppe Manco, and Ettore Ritacco</i>	968
Community Detection in Biological Networks <i>Marco Pellegrini</i>	978
Protein–Protein Interaction Databases <i>Max Kotlyar, Chiara Pastrello, Andrea EM Rossos, and Igor Jurisica</i>	988
Alignment of Protein-Protein Interaction Networks <i>Swarup Roy, Hazel N Manners, Ahed Elmsallati, and Jugal K Kalita</i>	997
Visualization of Biomedical Networks <i>Anne-Christin Hauschild, Chiara Pastrello, Andrea EM Rossos, and Igor Jurisica</i>	1016
Cluster Analysis of Biological Networks <i>Asuda Sharma, Hesham Ali, and Dario Gheri</i>	1036

Biological Pathways	
<i>Giuseppe Agapito</i>	1047
Biological Pathway Data Formats and Standards	
<i>Ramakanth C Venkata and Dario Gheri</i>	1063
Biological Pathway Analysis	
<i>Ramakanth Chirravuri Venkata and Dario Gheri</i>	1067
Two Decades of Biological Pathway Databases: Results and Challenges	
<i>Sara Rahmati, Chiara Pastrello, Andrea EM Rossos, and Igor Jurisica</i>	1071
Visualization of Biological Pathways	
<i>Giuseppe Agapito</i>	1085
Integrative Bioinformatics	
<i>Marco Masseroli</i>	1092
Integrative Bioinformatics of Transcriptome: Databases, Tools and Pipelines	
<i>Maria T Di Martino and Pietro H Guzzi</i>	1099
Information Retrieval in Life Sciences	
<i>Pietro Cinaglia, Domenico Mirarchi, and Pierangelo Veltri</i>	1104

LIST OF CONTRIBUTORS FOR VOLUME 1

Giuseppe Agapito

*University "Magna Graecia" of Catanzaro,
Catanzaro, Italy*

Hesham Ali

*University of Nebraska at Omaha, Omaha, NE,
United States*

Alessia Amelio

University of Calabria, Rende, Italy

Claudia Angelini

*Istituto per le Applicazioni del Calcolo "M. Picone",
Napoli, Italy*

Fabrizio Angiulli

University of Calabria, Rende, Italy

Matteo Baldoni

University of Turin, Turin, Italy

Cristina Baroglio

University of Turin, Turin, Italy

Denis Bauer

CSIRO, North Ryde, NSW, Australia

Stefano Beretta

University of Milan-Biocca, Milan, Italy

Federico Bergenti

University of Parma, Parma, Italy

Anna Bernasconi

Politecnico di Milano, Milan, Italy

Daniel Berrar

Tokyo Institute of Technology, Tokyo, Japan

Dhruba K. Bhattacharyya

Tezpur University, Tezpur, India

Mariaconcetta Bilotta

*University of Catanzaro, Catanzaro, Italy; and Institute
S. Anna of Crotona, Crotona, Italy*

Francesco Buccafurri

University of Reggio Calabria, Italy

Massimo Cafaro

University of Salento, Lecce, Italy

Barbara Calabrese

*University "Magna Graecia" of Catanzaro,
Catanzaro, Italy*

Mario Cannataro

*University "Magna Graecia" of Catanzaro, Catanzaro,
Italy*

Maria Francesca Carfora

*Istituto per le Applicazioni del Calcolo CNR, Napoli,
Italy*

Mauro Castelli

*NOVA IMS, Universidade Nova de Lisboa, Lisboa,
Portugal*

Giuseppe Cattaneo

University of Salerno, Fisciano, Italy

Francesco Cauteruccio

University of Calabria, Rende, Italy

Danilo Cavaliere

Università degli Studi di Salerno, Fisciano, Italy

Davide Chicco

Princess Margaret Cancer Centre, Toronto, ON, Canada

PREFACE

Bioinformatics and Computational Biology (BCB) combine elements of computer science, information technology, mathematics, statistics, and biotechnology, providing the methodology and *in silico* solutions to mine biological data and processes, for knowledge discovery. In the era of molecular diagnostics, targeted drug design and Big Data for personalized or even precision medicine, computational methods for data analysis are essential for biochemistry, biology, biotechnology, pharmacology, biomedical science, and mathematics and statistics. Bioinformatics and Computational Biology are essential for making sense of the molecular data from many modern high-throughput studies of mice and men, as well as key model organisms and pathogens. This Encyclopedia spans basics to cutting-edge methodologies, authored by leaders in the field, providing an invaluable resource to students as well as scientists, in academia and research institutes as well as biotechnology, biomedical and pharmaceutical industries.

Navigating the maze of confusing and often contradictory jargon combined with a plethora of software tools is often confusing for students and researchers alike. This comprehensive and unique resource provides up-to-date theory and application content to address molecular data analysis requirements, with precise definition of terminology, and lucid explanations by experts.

No single authoritative entity exists in this area, providing a comprehensive definition of the myriad of computer science, information technology, mathematics, statistics, and biotechnology terms used by scientists working in bioinformatics and computational biology. Current books available in this area as well as existing publications address parts of a problem or provide chapters on the topic, essentially addressing practicing bioinformaticists or computational biologists. Newcomers to this area depend on Google searches leading to published literature as well as several textbooks, to collect the relevant information.

Although curricula have been developed for Bioinformatics education for two decades now (Altman, 1998), offering education in bioinformatics continues to remain challenging from the multidisciplinary perspective, and is perhaps an NP-hard problem (Ranganathan, 2005). A minimum Bioinformatics skill set for university graduates has been suggested (Tan *et al.*, 2009). The Bioinformatics section of the Reference Module in Life Sciences (Ranganathan, 2017) commenced by addressing the paucity of a comprehensive reference book, leading to the development of this Encyclopedia. This compilation aims to fill the “gap” for readers with succinct and authoritative descriptions of current and cutting-edge bioinformatics areas, supplemented with the theoretical concepts underpinning these topics.

This Encyclopedia comprises three sections, covering Methods, Topics and Applications. The theoretical methodology underpinning BCB are described in the Methods section, with Topics covering traditional areas such as phylogeny, as well as more recent areas such as translational bioinformatics, cheminformatics and computational systems biology. Additionally, Applications will provide guidance for commonly asked “how to” questions on scientific areas described in the Topics section, using the methodology set out in the Methods section. Throughout this Encyclopedia, we have endeavored to keep the content as lucid as possible, making the text “... as simple as possible, but not simpler,” attributed to Albert Einstein. Comprehensive chapters provide overviews while details are provided by shorter, encyclopedic chapters.

During the planning phase of this Encyclopedia, the encouragement of Elsevier’s Priscilla Braglia and the constructive comments from no less than ten reviewers lead our small preliminary editorial team (Christian Schönbach, Kenta Nakai and myself) to embark on this massive project. We then welcomed one more Editor-in-Chief, Michael Gribskov and three section editors, Mario Cannataro, Bruno Gaeta and Asif Khan, whose toils have results in gathering most of the current content, with all editors reviewing the submissions. Throughout the production phase, we have received invaluable support and guidance as well as milestone reminders from Paula Davies, for which we remain extremely grateful.

Finally we would like to acknowledge all our authors, from around the world, who dedicated their valuable time to share their knowledge and expertise to provide educational guidance for our readers, as well as leave a lasting legacy of their work.

We hope the readers will enjoy this Encyclopedia as much as the editorial team have, in compiling this as an ABC of bioinformatics, suitable for naïve as well as experienced scientists and as an essential reference and invaluable teaching guide for students, post-doctoral scientists, senior scientists, academics in universities and research institutes as well as pharmaceutical, biomedical and biotechnological industries. Nobel laureate Walter Gilbert predicted in 1990 that “In the year 2020 you will be able to go into the drug store, have your DNA sequence read in an hour or so, and given back to you on a compact disk so you can analyze it.” While technology may have already arrived at this milestone, we are confident one of the readers of this Encyclopedia will be ready to extract valuable biological data by computational analysis, resulting in biomedical and therapeutic solutions, using bioinformatics to “measure” health for early diagnosis of “disease.”

Shoba Ranganathan

Introduction

Biology offers a huge amount and variety of data to be processed. Such data has to be stored, analysed, compared, searched, classified, etcetera, feeding with new challenges many fields of computer science. Among them, algorithmics plays a special role in the analysis of biological sequences, structures, and networks. Indeed, especially due to the flood of data coming from sequencing projects as well as from its down-stream analysis, the size of digital biological data to be studied requires the design of very efficient algorithms. Moreover, biology has become, probably more than any other fundamental science, a great source of new algorithmic problems asking for accurate solutions. Nowadays, biologists more and more need to work with *in silico* data, and therefore it is important for them to understand why and how an algorithm works, in order to be confident in its results. The goal of this chapter is to give an overview of fundamentals of algorithms design and evaluation to a non-computer scientist.

Algorithms and Their Complexity

Computationally speaking, a *problem* is defined by an input/output relation: we are given an input, and we want to return as output a well defined solution which is a function of the input satisfying some property.

An *algorithm* is a computational procedure (described by means of an unambiguous sequence of instructions) that has to be executed in order to solve a computational problem. An algorithm solving a given problem is correct if it outputs the right result for every possible input. The algorithm has to be described according to the entity which will execute it: if this is a computer, then the algorithm will have to be written in a programming language.

Example: Sorting Problem

INPUT: A sequence S of n numbers $\langle a_1, a_2, \dots, a_n \rangle$.

OUTPUT: A permutation $\langle a'_1, a'_2, \dots, a'_n \rangle$ of S such that $a'_1 \leq a'_2 \leq \dots \leq a'_n$.

Given a problem, there can be many algorithms that correctly solve it, but in general they will not all be equally efficient. The efficiency of an algorithm is a function of its input size.

For example, a solution for the sorting problem would be to generate all possible permutations of S and, per each one of them, check whether this is sorted. With this procedure, one needs to be lucky to find the right sorting fast, as there is an exponential (in n) number of such permutations and in the average case, as well as in the worst case, this algorithm would require a number of elementary operations (such as write a value in a memory cell, comparing two values, swapping two values, etcetera) which is exponential in the input size n . In this case, since the worst case cannot be excluded, we say that the algorithm has an exponential *time complexity*. In computer science, exponential algorithms are considered *intractable*. An algorithm is, instead, *tractable*, if its complexity function is polynomial in the input size. The *complexity of a problem* is that of the most efficient algorithm that solves it. Fortunately, the sorting problem is tractable, as there exist tractable solutions that we will describe later.

In order to evaluate the running time of an algorithm independently from the specific hardware on which it is executed, this is computed in terms of the amount of simple operations to which it is assigned an unitary cost or, however, a cost which is constant with respect to the input size. A constant running time is a negligible cost, as it does not grow when the input size does; moreover, a constant factor summed up with a higher degree polynomial in n is also negligible; furthermore, even a constant factor multiplying a higher polynomial is considered negligible in running time analysis. What counts is the growth factor with respect to the input size, i.e. the *asymptotic* complexity $T(n)$ as the input size n grows. In computational complexity theory, this is formalized using the *big-O* notation that excludes both coefficients and lower order terms: the asymptotic time complexity $T(n)$ of an algorithm is in $O(f(n))$ if there exist n_0 and $c > 0$ such that $T(n) \leq c f(n)$ for all $n \geq n_0$. For example, an algorithm that scans an input of size n a constant number of times, and then performs a constant number of some other operations, takes $O(n)$ time, and is said to have linear time complexity. An algorithm that takes linear time only in the worst case is also said to be in $O(n)$, because the big-O notation represents an upper bound. There is also an asymptotic complexity notation $\Omega(f(n))$ for the lower bound: $T(n) = \Omega(f(n))$ whenever $f(n) = O(T(n))$. A third notation $\Theta(f(n))$ denotes asymptotic equivalence: we write $T(n) = \Theta(f(n))$ if both $T(n) = O(f(n))$ and $f(n) = O(T(n))$ hold. For example, an algorithm that *always* performs a linear scan of the input, and not just in the worst case, has time complexity in $\Theta(n)$. Finally, an algorithm which needs to at least read, hence scan, the whole input of size n (and possibly also perform more costly tasks), has time complexity in $\Omega(n)$.

Time complexity is not the only cost parameter of an algorithm: *space complexity* is also relevant to evaluate its efficiency. For space complexity, computer scientists do not mean the size of the program describing an algorithm, but rather the data structures this actually keeps in memory during its execution. Like for time complexity, the concern is about how much memory the execution takes in the worst case and with respect to the input size. For example, an algorithm solving the sorting problem without

requiring any additional data structure (besides possibly a constant number of constant-size variables), would have linear space complexity. Also the exponential time complexity algorithm we described above has linear space complexity: at each step, it suffices to keep in memory only one permutation of S , as those previously attempted can be discarded. This observation offers an example of why, often, time complexity is of more concern than space complexity. The reason is not that space is less relevant than time, but rather that space complexity is in practice a lower bound of (and thus smaller than) time complexity: if an algorithm has to write and/or read a certain amount of data, then it forcibly has to perform at least that amount of elementary steps (Cormen *et al.*, 2009; Jones and Pevzner, 2004).

Iterative Algorithms

An *iterative algorithm* is an algorithm which repeats a same sequence of actions several times; the number of such times does not need to be known a priori, but it has to be finite. In programming languages, there are basically two kinds of iterative commands: the **for** command repeats the actions a number of times which is computed, or anyhow known, before the iterations begin; the **while** command, instead, performs the actions as long as a certain given condition is satisfied, and the number of times this will occur is not known a priori. What we call here an *action* is a command which can be, on its turn, again iterative. The cost of an iterative command is the cost of its actions multiplied by the number of iterations.

From now on, in this article we will describe an algorithm by means of the so-called *pseudocode*: an informal description of a real computer program, which is a mixture of natural language and keywords representing commands that are typical of programming languages. To this purpose, before exhibiting an example of an iterative algorithm for the sorting problem, we introduce the syntax of a fundamental elementary command: the assignment " $x \leftarrow E$ ", whose effect is to set the value of an expression E to the variable x , and whose time cost is constant, provided that computing the value of E , which can contain on its turn variables as well as calls of functions, is also constant. We will assume that the input sequence S of the sorting problem is given as an array: an array is a data structure of known fixed length that contains elements of the same type (in this case numbers). The i -th element of array S is denoted by $S[i]$, and reading or writing $S[i]$ takes constant time. Also swapping two values of the array takes constant time, and we will denote this as a single command in our pseudocode, even if in practice it will be implemented by a few operations that use a third temporary variable. What follows is the pseudocode of an algorithm that solves the sorting problem in polynomial time.

```

INSERTION-SORT( $S, n$ )
  for  $i = 1$  to  $n - 1$  do
     $j \leftarrow i$ 
    while ( $j > 0$  and  $S[j - 1] > S[j]$ )
      swap  $S[j]$  and  $S[j - 1]$ 
       $j \leftarrow j - 1$ 
    end while
  end for

```

INSERTION-SORT takes in input the array S and its size n . It works iteratively by inserting into the partially sorted S the elements one after the other. The array is indexed from 0 to $n - 1$, and a **for** command performs actions for each i in the interval $[1, n - 1]$ so that at the end of iteration i , the left end of the array up to its i -th position is sorted. This is realized by means of another iterative command, nested into the first one, that uses a second index j that starts from i , compares $S[j]$ (the new element) with its predecessor, and possibly swaps them so that $S[j]$ moves down towards its right position; then j is decreased and the task is repeated until $S[j]$ has reached its correct position; this inner iterative command is a **while** command because this task has to be performed as long as the predecessor of $S[j]$ is larger than it.

Example: Let us consider $S = [3, 2, 7, 1]$. Recall that arrays are indexed from position 0 (that is, $S[0] = 3$, $S[1] = 1$, and so on). INSERTION-SORT for $i = 1$ sets $j = 1$ as well, and then executes the while because $j = 1 > 0$ and $S[0] > S[1]$: these two values are swapped and j becomes 0 so that the while command ends with $S = [2, 3, 7, 1]$. Then a new **for** iteration starts with $i = 2$ (notice that at this time, correctly, S is sorted up to $S[1]$), and $S[2]$ is taken into account; this time the **while** command is entered with $j = 2$ and its condition is not satisfied (as $S[2] > S[1]$) so that the **while** immediately ends without changing S : the first three values of S are already sorted. Finally, the last **for** iteration with $i = 4$ will execute the **while** three times (that is, $n - 1$) swapping 1 with 7, then with 3, and finally with 2, leading to $S = [1, 2, 3, 7]$ which is the correct output.

INSERTION-SORT takes at least linear time (that is, its time complexity is in $\Omega(n)$) because all elements of S must be read, and indeed the **for** command is executed $\Theta(n)$ times: one per each array position from the second to the last. The invariant is that at the beginning of each such iteration, the array is sorted up to position $S[i - 1]$, and then the new value at $S[i]$ is processed. Each iteration of the **for**, besides the constant time (hence negligible) assignment $j \leftarrow i$, executes the **while** command. This latter checks its condition (in constant time) and, if the newly read element $S[j]$ is greater than, or equal to, $S[j - 1]$ (which is the largest of the so far sorted array), then it does nothing; else, it swaps $S[j]$ and $S[j - 1]$, decreases j , checks again the condition, and possibly repeats these actions, as long as either $S[j]$ finds its place after a smaller value, or it becomes the new first element of S as it is the smallest found so far. Therefore, the actions of the **while** command are never executed if the array is already sorted. This is the best case time complexity of INSERTION-SORT: linear in the input size n . The worst case is, instead, when the input array is sorted in

the reverse order: in this case, at each iteration i , the **while** command has to perform exactly i swaps to let $S[j]$ move down to the first position. Therefore, in this case, iteration i of the **for** takes i steps, and there are $n - 1$ such iterations for each $1 \leq i \leq n - 1$. Hence, the worst case running time is

$$\sum_{i=1}^{n-1} i = \frac{n(n-1)}{2} = \Theta(n^2)$$

As for space complexity, INSERTION-SORT works within the input array plus a constant number of temporary variables, and hence it has linear space complexity. Being n also a lower bound (the whole array must be stored), in this case the space complexity is optimal.

The algorithm we just described is an example of iterative algorithm that realises a quite intuitive sorting strategy; indeed, often this algorithm is explained as the way we would sort playing cards in one hand by using the other hand to iteratively insert each new card in its correct position. Iteration is powerful enough to achieve, for our sorting problem, a polynomial time – although almost trivial – solution; the time complexity of INSERTION-SORT cannot however be proved to be optimal as the lower bound for the sorting problem is not n^2 , but rather $n \cdot \log_2 n$ (result not proved here). In order to achieve $O(n \cdot \log_2 n)$ time complexity we need an even more powerful paradigm that we will introduce in next section.

Recursive Algorithms

A *recursive algorithm* is an algorithm which, among its commands, recursively calls itself on smaller instances: it splits the main problem into subproblems, recursively solves them and combines their solutions in order to build up the solution of the original problem. There is a fascinating mathematical foundation, that goes back to the arithmetic of Peano, and even further back to induction theory, for the conditions that guarantee correctness of a recursive algorithm. We will omit details of this involved mathematical framework. Surprisingly enough, for a computer this apparently very complex paradigm, is easy to implement by means of a simple data structure (the *stack*).

In order to show how powerful induction is, we will use again our Sorting Problem running example. Namely, we describe here the recursive MERGE-SORT algorithm which achieves $\Theta(n \cdot \log_2 n)$ time complexity, and is thus optimal. Basically, the algorithm MERGE-SORT splits the array into two halves, sorts them (by means of two recursive calls on as many sub-arrays of size $n/2$ each), and then merges the outcomes into a whole sorted array. The two recursive calls, on their turn, will recursively split again into subarrays of size $n/4$, and so on, until the base case (the already sorted sub-array of size 1) is reached. The merging procedure will be implemented by the function MERGE (pseudocode not shown) which takes in input the array and the starting and ending positions of its portions that contain the two contiguous sub-arrays to be merged. Recalling that the two half-arrays to be merged are sorted, MERGE simply uses two indices along them sliding from left to right, and, at each step: makes a comparison, writes the smallest, and increases the index of the sub-array which contained it. This is done until when both sub-arrays have been entirely written into the result.

```

MERGE-SORT(S,p,r)
  if p < r then
    q ← ⌊(p+r)/2⌋
    MERGE-SORT(S,p,q)
    MERGE-SORT(S,q+1,r)
    MERGE(S,p,q,r)
  end if

```

Given the need of calling the algorithm on different array fragments, the input parameters, besides S itself, will be the starting and ending position of the portion of array to be sorted. Therefore, the first call will be $\text{MERGE-SORT}(S, 0, n-1)$. Then the index q which splits S in two halves is computed, and the two so found subarrays are sorted by means of as many recursive calls; the two resulting sorted arrays of size $n/2$ are then fused by MERGE into the final result. The correctness of the recursion follows from the fact that the recursive call is done on a half-long array, and from the termination condition “ $p < r$ ”: if this holds, then the recursion goes on; else ($p = r$) there is nothing to do as the array has length 1 and it is sorted. Notice, indeed, that if S is not empty, then $p > r$ can never hold as q is computed such that $p \leq q < r$.

The algorithm MERGE-SORT has linear (hence optimal) space complexity as it only uses S itself plus a constant number of variables. The time complexity $T(n)$ of MERGE-SORT can be defined by the following recurrence relation:

$$T(n) = \begin{cases} \Theta(1) & \rightarrow n = 1 \\ 2 \cdot T(n/2) + \Theta(n) & \rightarrow n > 1 \end{cases}$$

because, with an input of size n , MERGE-SORT calls itself twice on arrays of size $n/2$, and then calls MERGE which takes, as we showed above, $\Theta(n)$ time.

We now show by induction on n that $T(n) = \Theta(n \cdot \log_2 n)$. The base case is simple: if $n = 1$ then S is already sorted and correctly MERGE-SORT does nothing and ends in $\Theta(1)$ time. If $n > 1$, assuming that $T(n') = \Theta(n' \cdot \log_2 n')$ holds for $n' < n$, then we have

$T(n) = 2 \cdot n/2 \cdot \log_2(n/2) + n = n(\log_2 n - \log_2 2 + 1)$, which is in $\Theta(n \cdot \log n)$. It follows that MERGE-SORT has optimal time complexity.

Closing Remarks

In this article we gave an overview of algorithms and their complexity, as well as of the complexity of a computational problem and how the latter should be stated. We also described two fundamental paradigms in algorithms design: iteration and recursion. We used as running example a specific problem (sorting an array of numbers) to exemplify definitions, describe algorithms using different strategies, and learning how to compute their complexity.

Biographical Sketch

Nadia Pisanti graduated cum laude in Computer Science at the University of Pisa in 1996. In 1998 she obtained a DEA degree at the University of Paris Est, and in 2002 a PhD in Informatics at the University of Pisa. She has been visiting fellow at the Pasteur Institute in Paris, ERCIM fellow at INRIA Rhone Alpes, research fellow at the University of Pisa, and CNRS post-doc at the University of Paris 13. Since 2006 she is with the Department of Computer Science of the University of Pisa. During the academic year 2012–2013 she was on sabbatical leave at Leiden University, and during that time she has been visiting fellow at CWI Amsterdam. Since 2015, she is part of the international INRIA team ERABLE. Her research interests fall in the field of Computational Biology and, in particular, in the design and application of efficient algorithms for the analysis of genomic data.

Techniques for Designing Bioinformatics Algorithms

Massimo Cafaro, Italo Epicoco, and Marco Pulimeno, University of Salento, Lecce, Italy

Introduction

This article deals with design techniques for algorithms, a fundamental topic which deserves an entire book. Indeed, several books have been published, including Cormen *et al.* (2009), Kleinberg (2011), Knuth (1998), Kozen (1992), Levitin (2006), Manber (1989), Mehlhorn and Sanders (2010), Sedgewick and Wayne (2011), and Skiena (2010). Owing to space limits, we can not hope to provide an in-depth discussion and thorough treatment of each of the design techniques that shall be presented. Rather, we aim at providing a modern introduction that, without sacrificing formal rigour when needed, emphasizes the pro and cons of each design technique, putting it in context. The interested reader may refer to the provided bibliography to delve into this fascinating topic.

Informally, an algorithm is the essence of a computational procedure, and can be thought as a set of step-by-step instructions to transform the input into the output according to the problem's statement. The first algorithm known is the Euclidean algorithm for computing the greatest common divisor, circa 400–300 B.C. The modern study of algorithms dates back to the early 1960s, when the limited availability and resources of the first computers were compelling reasons for the users to strive to design efficient computer algorithms.

The systematic study of computer algorithms to solve literally thousands of problems in many different contexts had begun, with extensive progress made by a huge number of researchers active in this field. A large number of efficient algorithms were devised to solve different problems, and the availability of many correct algorithms for the same problem stimulated the theoretical analysis of algorithms.

Looking at the similarities among different algorithms designed to solve certain classes of problems, the researchers were able to abstract and infer general algorithm design techniques. We cover here the most common techniques in the design of sequential algorithms.

Exhaustive Search

We begin our discussion of design techniques for algorithms starting with *exhaustive search*, which is also known as the *brute force* approach. The technique, from a conceptual perspective, represents the simplest possible approach to solve a problem. It is a straightforward algorithmic approach which, in general, involves trying all of the possible candidate solutions to the problem being solved and returning the best one. The name exhaustive search is therefore strictly related to the modulus operand of the technique, which exhaustively examines and considers all of the possible candidate solutions. The actual number of solutions returned depends on the problem's statement.

For instance, consider the problem of determining all of the divisors of a natural number n . Exhaustive search solves the problem by trying one by one each integer x from 1 to n and verifying if x divides exactly n , i.e., if n modulo x returns a remainder equal to zero. Each x satisfying the problem's statement is outputted. Therefore, for this problem exhaustive search returns a set of solutions, according to the problem's statement.

However, it is worth noting here that the technique may also be used to solve other problems which admit one or more optimal solutions (e.g., the class of optimization problems). In this case, we are not usually concerned with determining all of the possible solutions, since we consider all of the solutions practically equivalent (from an optimality perspective with regard to the problem's statement). For these problems, exhaustive search consists of trying one by one all of the possible solutions and returning one of the satisfying candidate solutions, typically the first encountered. Once a solution is returned, remaining candidates (if any) are simply discarded from further consideration. Of course, if the problem admits exactly one solution, discarding the remaining candidates which can not be the solution allows avoiding a waste of time.

For instance, consider the sorting problem. We are given an input sequence $a_1, a_2, \dots, a_n$ of n elements, and must output a permutation $a_1^*, a_2^*, \dots, a_n^*$ such that $a_1^* \leq a_2^* \leq \dots \leq a_n^*$. One may try all of the possible permutations of the input sequence, stopping as soon as the one under consideration satisfies the output specification and can therefore be returned as the solution to the problem.

Exhaustive search is therefore a design technique characterized by its conceptual simplicity and by the assurance that, if a solution actually exists, it will be found. Nonetheless, enumerating all of the possible candidate solutions may be difficult or costly, and the cost of exhaustive search is proportional to the number of candidates. For instance, for the problem of determining all of the divisors of a natural number n , the number of candidates is n itself. The cost of exhaustive search for this problem depends on the actual number of bits required to store n and on the division algorithm used (it is worth recalling here that a division costs $O(1)$ only for sufficiently small n since we can not assume constant time arbitrary precision arithmetic when the size of n grows). Regarding the sorting problem, since there are $n!$ possible permutations of the input sequence, the worst case computational complexity is exponential in the input, making this approach to the problem unsuitable for large problems as well.

Since for many problems of practical interest a small increase in the problem size corresponds to a large increase in the number of candidates, the applicability of this technique is strictly confined to small size problems. Even though exhaustive search is often inefficient as an algorithmic design technique, it may be used as a useful complementary test to check that the results reported by other efficient algorithms - when run on small inputs - are indeed correct. Taking into account that exhaustive search is based on the enumeration of all of the possible candidate solutions, which are then checked one by one, in order to start applying the technique it is a useful discipline learning (by practice) how to identify the *structure* of a solution and how to rank a solution in order to select the best one.

A notable example of exhaustive search is the *linear search* algorithm for searching an element in an unsorted array (Knuth, 1998). A good example in bioinformatics is the so-called *restriction mapping problem* (Danna et al., 1973). Restriction enzyme mapping was a powerful tool in molecular biology for the analysis of DNA, long before the first bacterial genome was sequenced. Such a technique relied on restriction endonucleases, each one recognizing and reproducibly cleaving a specific base pair sequence in double-stranded DNA generating fragments of varying sizes. Determining the lengths of these DNA fragments is possible, taking into account that the rate at which a DNA molecule moves through an agarose gel during the electrophoresis process is inversely proportional to its size. Then, this information can be exploited to determine the positions of cleavage sites in a DNA molecule. Given only pairwise distances between a set of points, the restriction mapping problem requires recovering the positions of the points, i.e., in other words we are required to reconstruct the set of points.

Let X be a set of n points on a line segment in increasing order, and ΔX the multiset (i.e., a set that allows duplicate elements) of all pairwise distances between points in X : $\Delta X = \{x_j - x_i : 1 \leq i < j \leq n\}$. How to reconstruct X from ΔX ? We start noting here that the set of points giving rise to the pairwise input distances is not necessarily unique since the following properties hold:

$$\begin{aligned}\Delta A &= \Delta(A \oplus \{v\}) \\ \Delta A &= \Delta(-A) \\ \Delta(A \oplus B) &= \Delta(A \ominus B)\end{aligned}\tag{1}$$

where $A \oplus B \equiv \{a + b : a \in A, b \in B\}$ and $A \ominus B \equiv \{a - b : a \in A, b \in B\}$. More in general, two sets A and B are said to be *homometric* if $\Delta A = \Delta B$, and biologists are usually interested in retrieving all of the homometric sets.

Even though highly inefficient for large n , an exhaustive search algorithm for this problem is conceptually simple. Let L and n be respectively the input list of distances, and n the cardinality of X . The algorithm determines M , the maximum element in L and then for every set of $n - 2$ integers taken from L such that $0 < x_2 < \dots < x_{n-1} < M$, it forms $X = \{0, x_2, \dots, x_{n-1}, M\}$ and checks if $\Delta X = L$. Of course, the complexity of this algorithm is exponential in n . A better (slightly more practical) exhaustive search algorithm for this problem has been designed by Skiena in 1990 (Skiena et al., 1990) (it is an exponential algorithm as well). The first polynomial-time algorithm efficiently solving this problem was designed by Daurat et al. in 2002 (Daurat et al., 2002).

Decrease and Conquer

In order to solve a problem, *decrease and conquer* (Levitin, 2006) works by reducing the problem instance to a smaller instance of the same problem, solving the smaller instance and extending the solution of the smaller instance to obtain the solution to the original instance. Therefore, the technique is based on exploiting a relationship between a solution to a given instance of a problem and a solution to a smaller instance of the same problem. This kind of approach can be implemented either top-down (recursively) or bottom-up (iteratively), and it is also referred to as the *inductive* or *incremental approach*.

Depending on the problem, decrease and conquer can be characterized by how the problem instance is reduced to a smaller instance:

1. Decrease by a constant (usually by one);
2. Decrease by a constant factor (usually by half);
3. Variable-size decrease.

We point out here the similarity between decrease and conquer in which decrease is by a constant factor and *divide and conquer*.

Algorithms that fall into the first category (decrease by a constant) include for instance: insertion sort (Cormen et al., 2009), graph traversal algorithms (DFS and BFS) (Cormen et al., 2009), topological sorting (Cormen et al., 2009), algorithms for generating permutations and subsets (Knuth, 1998). Among the algorithms in the second category (decrease by a constant factor) we recall here exponentiation by squaring (Levitin, 2006), binary search (Knuth, 1998), the strictly related bisection method and the russian peasant multiplication (Levitin, 2006). Finally, examples of algorithms in the last category (variable-size decrease) are the Euclid's algorithm (Cormen et al., 2009), the selection algorithm (Cormen et al., 2009), and searching and insertion in a binary search tree (Cormen et al., 2009).

Insertion sort exemplifies the decrease by a constant approach (in this case, decrease by one). In order to sort an array A of length n , the algorithm assumes that the smaller problem related to sorting the subarray $A[1 \dots n - 1]$ consisting of the first $n - 1$ elements has been solved; therefore, $A[1 \dots n - 1]$ is a sorted subarray of size $n - 1$. Then, the problem reduces to finding the appropriate position (i.e., the index) for the element $A[n]$ within the sorted elements of $A[1 \dots n - 1]$, and inserting it. Even though this leads naturally to a recursive, top-down implementation, Insertion sort is often implemented iteratively using a bottom-up

approach instead: it is enough to start inserting the elements, one by one, from $A[2]$ to $A[n]$. Indeed, in the first iteration, $A[1]$ is already a sorted subarray, since an array consisting of just one element is already sorted. The worst-case complexity of Insertion sort is $O(n^2)$ to sort n elements; optimal sorting algorithms with worst-case complexity $O(n \lg n)$ are Merge sort and Heap sort.

Exponentiation by squaring is an example of an algorithm based on decrease by a constant factor (decrease by half). The algorithm is based on the following equation to compute a^n , which takes into account the parity of n :

$$a^n = \begin{cases} a^{n/2} \cdot a^{n/2} & \text{if } n \text{ is even and positive} \\ a^{(n-1)/2} \cdot a^{(n-1)/2} \cdot a & \text{if } n \text{ is odd} \\ 1 & \text{if } n = 0 \end{cases}$$

Therefore, a^n can be computed recursively by an efficient algorithm requiring $O(\lg n)$ iterations since the size of the problem is reduced in each iteration by about a half, even though at the expense of one or two multiplications.

The Euclid's algorithm for computing the greatest common divisor of two numbers m and n such that $m > n$ (otherwise, we simply swap m and n before starting the algorithm), provides an example of variable-size decrease. Denoting by $\gcd(m, n)$ the greatest common divisor of m and n , and by $m \bmod n$ the remainder of the division of m by n , the algorithm is based on repeated application of the following equation:

$$\gcd(m, n) = \gcd(n, m \bmod n)$$

until $m \bmod n = 0$. Since $\gcd(m, 0) = m$, the last value of m is also the greatest common divisor of the initial m and n . Measuring an instance size of the problem of determining $\gcd(m, n)$ by the size of m , it can be easily proved that an instance size will always decrease by at least a factor of two after two successive iterations of Euclid's algorithm. Moreover, a consecutive pair of Fibonacci numbers provides a worst-case input for the algorithm with regard to the total number of iterations required.

Transform and Conquer

A group of techniques, known as *transform and conquer* (Levitin, 2006), can be used to solve a problem by applying a *transformation*; in particular, given an input instance, we can transform it to:

1. a simpler or more suitable/convenient instance of the same problem, in which case we refer to the transformation as *instance simplification*;
2. a different representation of the same input instance, which is a technique also known in the literature as *representation change*;
3. a completely different problem, for which we already know an efficient algorithm; in this case, we refer to this technique as *problem reduction*.

As an example of instance simplification, we discuss *gaussian elimination*, in which we are given a system of n linear equations in n unknowns with an arbitrary coefficient matrix. We apply the technique and transform the input instance to an equivalent system of n linear equations in n unknowns with an upper triangular coefficient matrix. Finally, we solve the latter triangular system by back substitution, starting with the last equation and moving up to the first one. Another example is *element uniqueness*. We are given an input array consisting of n elements, and we want to determine if all of the elements are unique, i.e., there are no duplicate elements in the array. Applying the exhaustive search technique we could compare all pairs of elements in worst-case running time $O(n^2)$. However, by instance simplification we can solve the problem in $O(n \lg n)$ as follows. First, we sort the array in time $O(n \lg n)$ using Merge Sort or Heap Sort, then we perform a linear scan of the array, checking pairs of adjacent elements, in time $O(n)$. Overall, the running time is $O(n \lg n) + O(n) = O(n \lg n)$.

Heap sort (Williams, 1964) provides an excellent example of representation change. This sorting algorithm is based on the use of a *binary heap* data structure, and it can be shown that a binary heap corresponds to an array and vice-versa, if certain conditions are satisfied.

Regarding problem reduction, this variation of transform and conquer solves a problem by transforming it into a different problem for which an algorithm is already available. However, it is worth noting here that problem reduction is valuable and practical only when the sum of the time required by the transformation (i.e., the reduction) and the time required to solve the newly generated problem is smaller than solving the input problem by using another algorithm. Examples of problem reductions include:

- computing $\text{lcm}(x, y)$ via computing $\gcd(x, y)$: $\text{lcm}(x, y) = \frac{|xy|}{\gcd(x, y)}$
- counting the number of paths of length n in a graph by raising the graph's adjacency matrix to the n th power;
- transforming a linear programming maximization problem to a minimization problem and vice-versa;
- reduction to graph problems (e.g., solving puzzles via state-space graphs).

Divide and Conquer

Divide and conquer (from Latin *divide et impera*) is an important design technique and works as follows. When the input instance is too big or complex to be solved directly, it is advantageous to divide the input instance into two or more subproblems of roughly the same size, solve the subproblems (usually recursively, unless the subproblems are small enough to be solved directly) and finally combine the solutions to the subproblems to obtain the solution for the original input instance.

Merge sort, invented by John von Neumann in 1945, is a sorting algorithm based on divide and conquer. In order to sort an array A of length n , the algorithm divides the input array into two halves $A[1 \dots \lfloor n/2 \rfloor - 1]$ and $A[\lfloor n/2 \rfloor \dots n]$, sorts them recursively and then merges the resulting smaller sorted arrays into a single sorted one. The key point is how to merge two sorted arrays, which can be easily done in linear time as follows. We scan both arrays using two pointers, initialized to point to the first elements of the arrays we are going to merge. We compare the elements and copy the smaller to the new array under construction; then, the pointer to the smaller element is incremented so that it points to the immediate successor element in the array. We continue comparing pairs of elements, determining the smaller and copying it to the new array until one of the two input arrays becomes empty. When this happens, we simply add the remaining elements of the other input array to the merged array. Let p and q be respectively the sizes of the two input array to be merged, such that $n = p + q$. Then, the merge procedure requires in the worst case $O(n)$ time.

Recursive algorithms such as Merge sort are analyzed by deriving and solving a recurrence equation. Indeed, recursive calls in algorithms can be described using recurrences, i.e., equations or inequalities that describe a function in terms of its value on smaller inputs. For instance, the recurrence for Merge sort is:

$$T(n) = \begin{cases} O(1) & n = 1 \\ 2T(n/2) + O(n) & n > 1 \end{cases} \quad (2)$$

Actually, the correct equation should be

$$T(n) = \begin{cases} O(1) & n = 1 \\ T(\lfloor n/2 \rfloor) + T(\lceil n/2 \rceil) + O(n) & n > 1 \end{cases} \quad (3)$$

but it can be shown that neglecting the floor and the ceil does not matter asymptotically.

There are many methods to solve recurrences. The most general method is the *substitution method*, in which we guess the form of the solution, verify it by induction and finally solve for the constants associated to the asymptotic notation. In order to guess the form of the solution, the *recursion-tree method* can be used; it models the cost (time) of a recursive execution of an algorithm. In the recursion tree each node represents a different substitution of the recurrence equation, so that each node corresponds to a value of the argument n of the function $T(n)$ associated with it. Moreover, each node q in the tree is also associated to the value of the nonrecursive part of the recurrence equation for q . In particular, for recurrences derived by a divide and conquer approach, the nonrecursive part is the one related to the work required to combine the solutions of the subproblems into the solution for the original problem, i.e., solutions related to the subproblems associated to the children of node q in the tree.

To generate the recursion tree, we start with $T(n)$ as the root node. Let the function $f(n)$ be the only nonrecursive term of the recurrence; we expand $T(n)$ and put $f(n)$ as the root of the recursion tree. We obtain the first level of the tree by expanding the recurrence, i.e. we put each of the recurrence terms involving the T function on the first level, and then we substitute them with the corresponding f terms. Then we proceed to expand the second level, substituting each T term with the corresponding f term. And so on, until we reach the leaves of the tree. To obtain an estimate of the solution to the recurrence, we sum the nonrecursive values across the levels of the tree and then sum the contribution of each level of the tree.

Equations of the form $T(n) = aT(n/b) + f(n)$, where $a \geq 1$, $b > 1$ and $f(n)$ is asymptotically positive can be solved immediately by applying the so-called *master theorem* (Cormen et al., 2009), in which we compare the function $f(n)$ with $n^{\log_b a}$. There are three cases to consider:

1. $\exists \epsilon > 0$ such that $f(n) = O(n^{\log_b a - \epsilon})$. In this case, $f(n)$ grows polynomially slower (by an n^ϵ factor) than $n^{\log_b a}$, and the solution is $T(n) = \Theta(n^{\log_b a})$;
2. $\exists k \geq 0$ such that $f(n) = \Theta(n^{\log_b a} \log^k n)$. Then, the asymptotic grow of both $f(n)$ and $n^{\log_b a}$ is similar, and the solution is $T(n) = \Theta(n^{\log_b a} \log^{k+1} n)$;
3. $f(n) = \Omega(n^{\log_b a + \epsilon})$ and $f(n)$ satisfies the regularity condition $af(n/b) \leq cf(n)$ for some constant $c < 1$. Then, $f(n)$ grows polynomially faster (by an n^ϵ factor) than $n^{\log_b a}$, and the solution is $T(n) = \Theta(f(n))$.

A more general method, devised by Akra and Bazzi (1998) allows solving recurrences of the form

$$T(n) = \sum_{i=1}^k a_i T(n/b_i) + f(n) \quad (4)$$

Let p be the unique solution to $\sum_{i=1}^k (a_i b_i^{-p}) = 1$; then the solution is derived exactly as in the master theorem, but considering n^p instead of $n^{\log_b a}$. Akra and Bazzi also prove an even more general result.

Many constant order linear recurrences are also easily solved by applying the following theorem.

Let $a_1, a_2, \dots, a_h \in \mathbb{N}$ and $h \in \mathbb{N}$, c and $\beta \in \mathbb{R}$ such that $c > 0$, $\beta \geq 0$ and let $a = \sum_{i=1}^h a_i$. Then, the solution to the recurrence

$$T(n) = \begin{cases} k \in \mathbb{N} & n \leq h \\ \sum_{i=1}^h a_i T(n-i) + cn^\beta & n > h \end{cases} \quad (5)$$

is

$$T(n) = \begin{cases} O(n^{\beta+1}) & a = 1 \\ O(a^n n^\beta) & a \geq 2 \end{cases} \quad (6)$$

Specific techniques for solving general constant order linear recurrences are also available.

Divide and conquer is a very powerful design technique, and for many problems it provides fast algorithms, including, for example, Merge sort, Quick sort (Hoare, 1962), binary search (Knuth, 1998), algorithms for powering a number (Levitin, 2006) and computing Fibonacci numbers (Gries and Levin, 1980), the Strassen's algorithm (Strassen, 1969) for matrix multiplication, the Karatsuba's algorithm (Karatsuba and Ofman, 1962) for multiplying two n bit numbers etc.

Since so many problems can be solved efficiently by divide and conquer, one can get the wrong impression that divide and conquer is always the best way to approach a new problem. However, this is of course not true, and the best algorithmic solution to a problem may be obtained by means of a very different approach.

As an example, consider the majority problem. Given an unsorted array of n elements, using only equality comparisons we want to find the majority element, i.e., the one which appears in the array more than $n/2$ times. An algorithm based on exhaustive search simply compares all of the possible pairs of elements and requires worst-case $O(n^2)$ running time. A divide and conquer approach provides an $O(n \log n)$ solution. However there exist an even better algorithm, requiring just a linear scan of the input array: the Boyer-Moore algorithm (Boyer and Moore, 1981, 1991) solves this problem in worst-case $O(n)$ time.

Randomized Algorithms

Randomized algorithms (Motwani and Raghavan, 2013) make random choices during the execution. In addition to its input, a randomized algorithm also uses a source of randomness:

- can flip coins as a basic step;
 - (i) can toss a fair coin c which is either Heads or Tails with probability $1/2$;
- can generate a random number r from a range $\{1 \dots R\}$;
 - (i) decisions and or computations are based on r 's value.

On the same input, on different executions, randomized algorithms may

- run for a different number of steps;
- produce different outputs.

Indeed, on different executions, different coins are flipped (different random numbers are used), and the value of these coins can change the course of executions. Why does it make sense to toss coins? Here are a few reasons. Some problems can not be solved deterministically at all; an example is the asynchronous agreement problem (consensus). For some other problems, only exponential deterministic algorithms are known, whereas polynomial-time randomized algorithms do exist. Finally, for some problems, a randomized algorithm provides a significant polynomial-time speedup with regard to a deterministic algorithm.

The intuition behind randomized algorithms is simple. Think of an algorithm as battling against an adversary who attempts to choose an input to slow it down as much as possible. If the algorithm is deterministic, then the adversary may analyze the algorithm and find an input that will elicit the worst-case behaviour. However, for a randomized algorithm the output does not depend only on the input, since it also depends on the random coins tossed. The adversary does not control and does not know which coins will be tossed during the execution, therefore his ability to choose an input which will elicit a worst-case running time is severely restricted. Where do we get coins from? In practice, randomized algorithms use pseudo random number generators.

Regarding the analysis of a randomized algorithm, this is different from average-case analysis, which requires knowledge of the distribution of the input and for which the expected running time is computed taking the expectation over the distribution of possible inputs. In particular, the running time of a randomized algorithm, being dependent on random bits, actually is a random variable, i.e., a function in a probability space Ω consisting of all of the possible sequences r , each of which is assigned a probability $Pr[r]$. The running time of a randomized algorithm A on input x and a sequence r of random bits, denoted by $A(x, r)$ is given by the expected value $E[A(x, r)]$, where the expectation is over r , the random choices of the algorithm: $E[A(x, r)] = \sum_{r \in \Omega} A(x, r) Pr[r]$.

There are two classes of randomized algorithms, which were originally named by Babai (1979).

- *Monte Carlo* algorithm: for every input, regardless of coins tossed, the algorithm always run in polynomial time, and the probability that its output is correct can be made arbitrarily high;

- *Las Vegas* algorithm: for every input, regardless of coins tossed, the algorithm is correct and it runs in expected polynomial time (for all except for a “small” number of executions, the algorithm runs in polynomial time).

The probabilities and expectations above are over the random choices of the algorithm, not over the input. As stated, a Monte Carlo algorithm fails with some probability, but we are not able to tell when it fails. A Las Vegas algorithm also fails with some probability, but we are able to tell when it fails. This allows us running it again until succeeding, which implies that the algorithm eventually succeeds with probability 1, even though at the expense of a potentially unbounded running time.

In bioinformatics, a good example of a Monte Carlo randomized algorithm is the *random projections* algorithm (Buhler and Tompa, 2001, 2002) for motif finding. Another common example of a Monte Carlo algorithm is the Freivald’s algorithm (Freivalds, 1977) for checking matrix multiplication. A classical example of Las Vegas randomized algorithm is Quick sort (Hoare, 1962), invented in 1962 by Charles Anthony Richard Hoare, which is also a divide and conquer algorithm. Even though the worst-case running time of Quick sort is $O(n^2)$, its expected running time is $O(n \lg n)$ as Merge sort and Heap sort. However, Quick sort is, in practice, much faster.

Dynamic Programming

The *Dynamic Programming* design technique provides a powerful approach to the solution of problems exhibiting (i) *optimal substructure* and (ii) *overlapping subproblems*. Property (i) (also known as *principle of optimality*) means that an optimal solution to the problem contains within it optimal solutions to related subproblems. Property (ii) tells us that the space of subproblems related to the problem we want to solve is small (typically, the number of distinct subproblems is a polynomial in the input size). In this context, a divide and conquer approach, which recursively solves all of the subproblems encountered in each recursive step, is clearly unsuitable and highly inefficient, since it will repeatedly solve all of the same subproblems whenever it encounters them again and again in the recursion tree. On the contrary, dynamic programming suggests solving each of the smaller subproblems only once and recording the results in a table from which a solution to the original problem can then be obtained.

Dynamic programming is often applied to optimization problems. Solving an optimization problem through dynamic programming requires finding an optimal solution, since there can be many possible solutions with the same optimal value (minimum or maximum, depending on the problem).

Computing the n th number of the Fibonacci series provides a simple example of application of dynamic programming (it is worth noting here that for this particular problem a faster divide and conquer algorithm, based on matrix exponentiation, actually exists). Denoting with $F(n)$ the n th Fibonacci number, it holds that $F(n) = F(n-1) + F(n-2)$. This problem is explicitly expressed as composition of subproblems, namely to compute the n th number we have to solve the same problem but with smaller instances $F(n-1)$ and $F(n-2)$. The divide and conquer approach would recursively compute all of the subproblems with a top-down approach, including also those subproblems already solved i.e. to compute $F(n)$ we have to compute $F(n-1)$ and $F(n-2)$; to compute $F(n-1)$ we have to compute again $F(n-2)$ and $F(n-3)$; in this example the subproblem $F(n-2)$ would be evaluated twice following the divide and conquer approach. Dynamic programming avoids recomputing the already solved subproblems. Typically dynamic programming follows a bottom-up approach, even though a recursive top-down approach with *memoization* is also possible (without memoizing the results of the smaller subproblems, the approach reverts to the classical divide and conquer).

As an additional example, we introduce the problem of *sequence alignment*. A common approach to infer a newly sequenced gene’s function is to find the similarities with genes of known function. Revealing the similarity between different DNA sequences is non trivial and comparing corresponding nucleotides is not enough; a sequence alignment is needed before comparison. Hirschberg’s space-efficient algorithm (Hirschberg, 1975) is a divide and conquer algorithm that can perform alignment in linear space (whilst the traditional dynamic programming approach requires quadratic space), even though at the expense of doubling the computational time.

The simplest form of a sequence similarity analysis is the Longest Common Subsequence (LCS) problem where only insertions and deletions between two sequences are allowed. We define a subsequence of a string v as an ordered sequence of characters, not necessarily consecutive, from v . For example, if $v = \text{ATTGCTA}$, then AGCA and ATTA are subsequences of v whereas TGTT and TCG are not. A common subsequence of two strings is a subsequence of both of them. The longer is a common substring between two strings, the more similar are the strings. We hence can formulate the Longest Common Substring problem as follows: given two input strings v and w , respectively of length n and m , find the longest subsequence common to the two strings.

Denoting with $s_{i,j}$ the longest common subsequence between the first i characters of v (denoted as i -prefix of v) and the first j characters of w (denoted as j -prefix of w), then the solution to the problem is $s_{n,m}$. We can solve the problem recursively noting that the following relation holds:

$$s_{i,j} = \begin{cases} s_{i-1,j-1} + 1 & \text{if } v_i = w_j \\ \max\{s_{i-1,j}, s_{i,j-1}\} & \text{if } v_i \neq w_j \end{cases} \quad (7)$$

Clearly, $s_{i,0} = s_{0,j} = 0 \forall 1 \leq i \leq n, 1 \leq j \leq m$. The first case corresponds to a match between v_i and w_j ; in this case, the solution for the subproblem $s_{i,j}$ is the solution for the subproblem $s_{i-1,j-1}$ plus one (since $v_i = w_j$ we can append v_i to the common substring we are building, increasing its length by one). The second case refers to a mismatch between v_i and w_j , giving rise to two possibilities: the

solution $s_{i-1,j}$ corresponds to the case in which v_i is not present in the LCS of the i -prefix of v and j -prefix of w , whilst the solution $s_{i,j-1}$ corresponds to the case when w_j is not present in LCS.

The problem has been expressed as composition of subinstances, moreover it can be easily proved that it meets the principle of optimality (i.e., if a string z is a LCS of v and w , then any prefix of z is a LCS of a prefix of v and w) and that the number of distinct LCS subproblems for two strings of lengths n and m is only nm . Hence the dynamic programming design technique can be applied to solve the problem.

In general, to apply dynamic programming, we have to address a number of issues:

1. Show optimal substructure, i.e. an optimal solution to the problem contains within it optimal solutions to subproblems; the solution to a problem is derived by:
 - making a choice out of a number of possibilities (look what possible choices there can be);
 - solving one or more subproblems that are the result of a choice (we need to characterize the space of subproblems);
 - show that solutions to subproblems must themselves be optimal for the whole solution to be optimal;
2. Write a recurrence equation for the value of an optimal solution:
 - $M_{opt} = \text{Min}$ (or Max , depending on the optimization problem) over all choices k of $\{(\text{sum of } M_{opt} \text{ of all of the subproblems resulting from choice } k) + (\text{the cost associated with making the choice } k)\}$;
 - show that the number of different instances of subproblems is bounded by a polynomial;
3. Compute the value of an optimal solution in a bottom-up fashion (alternatively, top-down with memoization);
4. Optionally, try to reduce the space requirements, by “forgetting” and discarding solutions to subproblems that will not be used any more;
5. Optionally, reconstruct an optimal solution from the computed information (which records a sequence of choices made that lead to an optimal solution).

Backtracking and Branch-and-Bound

Some problems require finding a feasible solution by exploring the solutions domain, which for these problems grows exponentially. For optimization problems we also require that the feasible solution is the best one according to an objective function. Many of these problems might not be solvable in polynomial time. In Section “Exhaustive Search” we discussed how such problems can be solved, in principle, by exhaustive search hence sweeping the whole solutions domain.

In this section we introduce the *Backtracking* and *Branch-and-Bound* design techniques which can be considered as an improvement of the exhaustive search approach. The main idea is to build the candidate solution to the problem adding one component at a time and evaluating the partial solution constructed so far. For optimization problems, we would also consider a way to estimate a bound on the best value of the objective function of any solution that can be obtained by adding further components to the partially constructed solution.

If the partial solution does not violate the problem constraints and its bound is better than the currently known feasible solution, then a new component can be added up to reach the final feasible solution. If during the construction of the solution no other component can be added either because it does not exist any feasible solution starting from the partially constructed solution or because its bound is worse than the currently known feasible solution, then the remaining components are not generated at all and the process backtracks, changing the previously added components. This approach makes it possible to solve some large instances of difficult combinatorial problems, though, in the worst case, we still face the same curse of exponential explosion encountered in exhaustive search.

Backtracking and Branch-and-Bound differ in the nature of problems they can be applied to. *Branch-and-Bound* is applicable only to optimization problems because it is based on computing a bound on possible values of the problem’s objective function. *Backtracking* is not constrained by this requirement and the partially built solution is pruned only if it violates the problem constraints.

Both methodologies require building the state-space tree whose nodes reflect the specific choices made for a solution’s components. Its root represents an initial state before the search for a solution begins. The nodes at the first level in the tree represent the choices made for the first component of a solution, and so on. A node in a state-space tree is said to be *promising* if it corresponds to a partially constructed solution that may still lead to a feasible solution; otherwise, it is called *nonpromising*. Leaves represent either *nonpromising* dead ends or complete solutions found by the algorithm.

We can better explain how to build the state-space tree by introducing the n -Queens problem. In the n -Queens problem we have to place n queens in an $n \times n$ chessboard so that no two queens attack each other. A queen may attack any chess piece if it is on the same row, column or diagonal. For this problem the *Backtracking* approach would bring valuable benefits with respect the exhaustive search. We know that only a queen must be placed in each row, we hence have to find the column where to place each queen so that the problem constraints are met.

A solution can be represented by n values $\{c_1, \dots, c_n\}$; where c_i represents the column of the i th queen. At the first level of the state-space tree we have n nodes representing all of the possible choices for c_1 . We make a choice for the first value of c_1 exploring

the first promising node and adding n nodes at second level corresponding to the available choices for c_2 . The partial solution made of c_1, c_2 choices is evaluated and the process continues visiting the tree in a depth-first manner. If all of the nodes on the current level are nonpromising, then the algorithm backtracks to the upper level up to the first promising node.

Several others problems can be solved by a backtracking approach. In the Subset-sum problem we have to find a subset of a given set $A = \{a_1, \dots, a_n\}$ of n positive integers whose sum is equal to a given positive integer d . The Hamiltonian circuit problem consists in finding a cyclic path that visits exactly once each vertex in a graph. In the n -Coloring problem we have to color all of the vertices in a graph such that no two adjacent vertices have the same color. Each vertex can be colored by using one of the n available colors. Subset-sum, Hamiltonian circuit and graph coloring are examples of NP-complete problems for which backtracking is a viable approach if the input instance is very small.

As a final example, we recall here the restriction map problem already described in Section “Exhaustive Search”. The restriction map problem is also known in computer science as Turnpike problem. The Turnpike problem is defined as follow: let X be a set of n points on a line $X = \{x_1, \dots, x_n\}$, given the ΔX multiset of the pairwise distances between each pair $\{x_i, x_j\}$, $\Delta X = \{x_j - x_i \mid i, j: 1 \leq i < j \leq n\}$, we have to reconstruct X .

Without loss of generality, we can assume that the first point in the line is at $x_1 = 0$. Let L be the input multiset with all of the distances between pairs of points; we have to find a solution X such that $\Delta X = L$. The key idea is to start considering the greatest distance in L ; let us denote it as δ_1 . We can state that the furthest point is at distance δ_1 , i.e. $x_n = \delta_1$. We remove δ_1 from L and consider the next highest distance δ_2 . This distance derives from two cases: $x_n - x_2 = \delta_2$ or $x_{n-1} - x_1 = \delta_2$; we can make an arbitrary choice and start building the state-space tree. Let us choose $x_2 = x_n - \delta_2$, we hence have a partial solution $\tilde{X} = \{0, \delta_1 - \delta_2, \delta_1\}$. In order to verify if this partial solution does not violate the constraints, we compute the $\Delta \tilde{X}$ and verify that $L \supset \Delta \tilde{X}$. If the constraint is satisfied, the node is a promising one and we can continue with the next point, otherwise we change the choice with the next promising node. The algorithm iterates until all of the feasible solutions are found. At each level of the state-space tree only two alternatives can be examined. Usually only one of the two alternatives is viable at any level. In this case the computational complexity of the algorithm can be expressed as:

$$T(n) = T(n-1) + O(n \log n) \quad (8)$$

being $O(n \log n)$ the time taken for checking the partial solution. In this case the computational complexity is $T(n) = O(n^2 \log n)$.

In the worst case both alternatives must be evaluated at each level; in this case the recurrence equation is:

$$T(n) = 2T(n-1) + O(n \log n) \quad (9)$$

whose solution is $T(n) = O(2^n n \log n)$. The algorithm remains an exponential time algorithm in the worst case like the one based on exhaustive search, but, usually, the backtracking approach greatly improves the computational time by pruning the non-promising branches. We recall finally that Daurat *et al.* in 2002 (Daurat *et al.*, 2002) proposed a polynomial algorithm to solve the restriction map problem.

In the majority of the cases, a state-space tree for a backtracking algorithm is constructed in a depth-first search manner, whilst Branch-and-Bound usually explores the state-space tree by using a best-first rule i.e. the node with the best bound is explored first. Compared to Backtracking, Branch-and-Bound requires two additional items:

- a way to provide, for every node of a state-space tree, a bound on the best value of the objective function on any solution that can be obtained by adding further components to the partially constructed solution represented by the node;
- the value of the best solution seen so far.

If the bound value is not better than the value of the best solution seen so far the node is *nonpromising* and can be pruned. Indeed, no solution obtained from it can yield a better solution than the one already available. Some of the most studied problems faced with the Branch-and-Bound approach are: the Assignment Problem in which we want to assign n people to n jobs so that the total cost of the assignment is as small as possible; in the Knapsack problem we have n items with weights w_i and values v_i , a knapsack of capacity W , and the problem consist in finding the most valuable subset of the items that fits in the knapsack; in the Traveling Salesman Problem (TSP) we have to find the shortest possible route that visits each city exactly once and returns to the origin city knowing the distances between each pair of cities. Assignment, Knapsack and TSP are examples of NP-complete problems for which Branch-and-Bound is a viable approach, if the input instance is very small.

Greedy Algorithms

The Greedy design technique defines a simple methodology related to the exploration of the solutions domain of optimization problems. The greedy approach suggests constructing a solution through a sequence of steps, each expanding a partially constructed solution obtained so far, until a complete solution to the problem is reached. Few main aspects make the greedy approach different from Branch-and-Bound. First, in the greedy approach no bound must be associated to the partial solution; second, the choice made at each step is irrevocable hence backtracking is not allowed in the greedy approach. During the construction of the solution, on each step the choice made must be:

- feasible: the partial solution has to met the problem's constraints;
- locally optimal: it has to be the best local choice among all of the feasible choices available on that step;

- irrevocable.

The Greedy approach is based on the hope that a sequence of locally optimal choices will yield an optimal solution to the entire problem. There are problems for which a sequence of locally optimal choices does yield an optimal solution for every input instance of the problem. However, there are others for which this is not the case and the greedy approach can provide a misleading solution. As an example, let us consider the change-making problem. Given a set of coins with decreasing value $C = \{c_i : c_i > c_{i+1} \forall i = 1, \dots, n\}$ and a total amount T , find the minimum number of coins to reach the total amount T . The solution is represented by a sequence of n occurrences of the corresponding coins. A greedy approach to the problem considers on step i the coin c_i and chooses its occurrences as the maximum possible subject to the constraint that the total amount accumulated so far must not exceed T . Let us suppose that we can use the following coins values $C = \{50, 20, 10, 5, 2, 1\}$ and that we have to change $T = 48$; a greedy approach suggests choosing on the first stage no coins of value 50, on the second step 2 coins of value 20 since this is the best choice to quickly reach the total amount T and so on until building the solution $S = \{0, 2, 0, 1, 1, 1\}$.

Greedy algorithms are both intuitively appealing and simple. Given an optimization problem, it is usually easy to figure out how to proceed in a greedy manner. What is usually more difficult is to prove that a greedy algorithm yields an optimal solution for all of the instances of the problem. The greedy approach applied to the change-making example given above provides optimal solution for any value of T , but what happens if the coins values are $C = \{25, 10, 1\}$ and the amount is $T = 40$? In this case following a greedy approach the solution would be $S = \{1, 1, 5\}$ but the best solution is instead $S = \{0, 4, 0\}$. Therefore, proving that the solution given by the greedy algorithm is optimal becomes a crucial aspect.

One of the common ways to do this is through mathematical induction, where we must prove that a partially constructed solution obtained by the greedy algorithm on each iteration can be extended to an optimal solution to the problem. The second way to prove optimality is to show that on each step it does at least as well as any other algorithm could in advancing toward the problem's goal. The third way is simply to show that the final result obtained is optimal based on the algorithm's output rather than on the way it operates. Finally, if a problem underlying combinatorial structure is a *matroid* (Cormen et al., 2009), then it is well known that the greedy approach leads to an optimal solution. The *matroid* mathematical structure has been introduced by Whitney in 1935; his *matric matroid* abstracts and generalizes the notion of linear independence.

In bioinformatic, one of the most challenging problem which can be solved through a greedy approach is genome rearrangement. Every genome rearrangement results in a change of gene ordering, and a series of these rearrangements can alter the genomic architecture of a species. The elementary rearrangement event is the flipping of a genomic segment, called a *reversal*. Biologists are interested in the smallest number of reversals between genomes of two species since it gives us a lower bound on the number of rearrangements that have occurred and indicates the similarity between two species.

In their simplest form, rearrangement events can be modelled by a series of reversals that transform one genome into another. Given a permutation $\pi = \pi_1 \pi_2 \dots \pi_{n-1} \pi_n$, a reversal $\rho(i, j)$ has the effect of reversing the order of block from i th to j th element $\pi_i \pi_{i+1} \dots \pi_{j-1} \pi_j$. For example the reversal $\rho(3, 5)$ of the permutation $\pi = 654298$ produces the new permutation $\pi \cdot \rho(3, 5) = 659248$. The Reversal Distance Problem can be formulated as follows: given two permutations π and σ , find the shortest series of reversals $\rho_1 \cdot \rho_2 \dots \rho_t$ that transforms π into σ . Without losing generality, we can consider the target permutation σ the ascending order of the elements. In this case the problem is also known as Sorting by Reversal. When sorting a permutation it hardly makes sense to move the elements already sorted. Denoting by $p(\pi)$ the number of already sorted elements of π , then a greedy strategy for sorting by reversals is to increase $p(\pi)$ at every step. Unfortunately, this approach does not guarantee that the solution is optimal. As an example we can consider $\pi = 51234$; following the greedy strategy we need four reversals for sorting π : $\{\rho(1,2), \rho(2,3), \rho(3,4), \rho(4,5)\}$ but we can easily see that two reversals are enough for sorting the permutation: $\{\rho(1,5), \rho(1,4)\}$.

Conclusions

We have presented a survey of the most important algorithmic design techniques, highlighting their pro and cons, and putting them in context. Even though, owing to space limits, we sacrificed in-depth discussion and thorough treatment of each technique, we hope to have provided the interested readers with just enough information to fully understand and appreciate the differences among the techniques.

Introduction

Ordered sequences of symbols (also called strings or sequences) play an important role in computer science. With an adequate semantics, they can be used to express several kinds of data. Data provided as sequences are constantly increasing in several areas of bioinformatics and computer science; think, for instance, of DNAs and proteins sequenced from organisms, but also at sensor networks, wearable devices, distributed agents, etc. Several general purpose techniques for string comparison have been proposed in the past literature.

In the specific context of bioinformatics, information encoded in biological sequences assumes an important role in identifying genetic-related diseases, and resulted useful for deciphering biological mechanisms. A gene is a sequence of DNA bases, used to generate proteins. The transformation from genes to proteins is based on transcription and gene expression mechanisms. Gene expression starts with one or more proteins, called transcription factors, binding to *transcription factor binding sites*; these are specific regions generally located before the gene sequence start. In fact, proteins may enhance or inhibit the transcription of a gene into a protein.

Regulation of gene expression, via the activation or inhibition of these transcription mechanisms, is a complex task, which is still under investigation by several researchers. However, it is well known that transcription factor binding sites are encoded as biologically significant patterns, called *motifs*, which occur in, or among, sequences frequently. As a matter of facts, researchers found that these are (usually small) sequences, which frequently occur in the same genome and are well conserved through evolution (see, for instance, [Pavesi et al., 2004](#); [Sandve and Drablos, 2006](#); [Sinha, 2002](#); [GuhaThakurta and Stormo, 2001](#)).

Several motif discovery approaches have been developed in the literature. These researches are strongly motivated by the availability of massive amounts of raw data resulting from the sequencing of the human genome, as well as of the genomes of other organisms. They significantly contributed to the growth of bioinformatics (see [Sandve et al., 2007](#); [Sandve and Drablos, 2006](#); [Pavesi et al., 2004](#), just to cite few papers).

Generally speaking, given a set of sequences, a motif discovery tool aims at identifying new, previously unknown, over-represented patterns; intuitively, these patterns should be common to all, or almost all, the sequences in the set. Motif discovery is not only used to detect transcription factor binding sites. As a matter of facts, the identification of over-represented patterns, through a set of protein sequences, might suggest that those proteins belong to the same family.

The search of frequent patterns has been also studied in other contexts, such as the analysis of time series (see [Torkamani and Lohweg, 2017](#)). However, the analysis of these approaches is out of the scope of this article.

The plan of this article is as follows. In Section Preliminary Definitions, we provide some preliminary notions related to motif discovery. In Section Approaches to Motif Search, we present an overview of motif search methods. In Section Assessing Motif Relevance, we illustrate the problems related to the assessment of motif relevance. Finally, in Section Closing Remarks, we provide some concluding remarks and we look at possible future directions of this research area.

Preliminary Definitions

Strings and Sequences

We start this section by introducing some notations and definitions, generally used in algorithms for motif discovery in strings and sequences.

An *alphabet* is a nonempty set (Σ) of elements called *symbols* (or *letters*).

A string s is an (finite) ordered sequence of symbols defined over (Σ), i.e., s consists of symbols of (Σ). We use the terms *strings* and *sequences* equivalently. For the sake of simplification, we represent a string by means of the juxtaposition of the symbols it consists of. For instance, suppose $(\Sigma) = \{a, b, c, d\}$, a string s , defined over (Σ), is $s = aabdbcdada$. The *length* of s is the number of symbols composing s , and is denoted by $|s|$. If $|s| = 0$, we call s the *empty string* and we denote it as $s = \varepsilon$. In biological contexts, relevant alphabets correspond to the four symbols representing DNA bases (A, C, G, T) and to the 20 symbols referring to aminoacids. We denote by $s[i]$, $1 \leq i \leq |s|$, the i -th symbol of s , i.e., the symbol at the position i in s .

A substring of s is a string that can be derived from s by deleting some symbols at the beginning and/or at the end of s . More formally, a string p is a *substring* (also called *factor*) of a string s whether $s = upw$, where u and w are two strings. If $u = \varepsilon$, p is called a *prefix* of s , whereas if $w = \varepsilon$, p is called a *suffix* of s . We denote by $s[i..j]$ the substring of s starting at index i and ending at index j . Let p be a nonempty string and let s be a string; we say that p has an *occurrence* in s (or, equivalently, that p *occurs in* s) if p is a substring of s .

A *subsequence* of s is a sequence that can be derived from s by deleting some symbols, without changing the order of the other symbols. Given two strings s and p , the Longest Common Subsequence between s and p (LCS) is the longest subsequence common to s and p .

Matches and Repetitions

An important problem on strings (strictly related to motif search) is that of *string matching*. Essentially, given two strings s and p , where s is called *text* and p is called *pattern*, string matching problem asks whether there exists an occurrence of p in s . This problem has been studied intensively in the literature, and we can distinguish between two main variants: *exact string matching* and *approximate string matching*. The former asks whether an exact occurrence of p can be found in s : here, “exact” means that $p = s[i..i + |p| - 1]$. Instead, the latter asks whether there exists a substring in s , which matches p via some matching function. Examples of simple matching functions are the Hamming distance, which counts the number of positions the two strings differ in, or the Longest Common Subsequence (LCS). In case of approximate matching with matching functions, some threshold is usually set (such as a maximum Hamming distance, or a minimum length of the LCS) to determine whether the match holds or not.

Approximate string matching can be carried out also by *string matching with don't care symbols*. In this case, occurrences of a special universal symbol $*$, called *don't care symbol*, can be included in the pattern p . A $*$ can match with any other (sequence of) symbol. Note that, in this context, the pattern becomes more complex, and harder computational issues may arise for determining the occurrences of p in s . For instance, given $s = \text{aabcdcd}$ and $p = a*c$, p occurs in s twice, one by substituting $*$ with bd and one by substituting $*$ with abd . Observe that, a don't care symbol may appear more than once in a pattern (e.g., $p = a*c*d$ occurs in s). A don't care symbol at the beginning and/or at the end of a pattern simply means that one may expect anything before and/or after the pattern; consequently, in pattern matching, don't care symbols in these positions are often omitted.

In some cases, in counting the number of occurrences of p in s , it may be important to distinguish between overlapping and non overlapping occurrences.

Motifs

Strings and matches are building blocks for the motif search problem (also called motif discovery). In bioinformatics, a motif is a biologically relevant pattern occurring in one or more input sequences; the set of sequences of interest for the motif search problem is also called sequence database. Two important research branches in motif discovery refer to *simple* and *structured* motifs. A simple motif is a single, usually short, sequence that significantly matches (either exactly or approximately) with the sequence database. A structured motif is a combination of simple motifs (called *boxes* or *blocks*), whose position and spacing (called also *gaps*) are relevant, and which are separated from one another by some regions not conserved in the evolution (Gross et al., 1992; Robin et al., 2003; Marsan and Sagot, 2000; Fassetti et al., 2008). Generally, the structures of motifs are *constrained*, which means that the minimum/maximum motif lengths, the box numbers, and the relative spacings are imposed.

In general, discovery methods are designed to identify motifs conforming to some model, which can capture the similarities of diverse sets of binding sites for the same transcription factor (see, for instance, Sandve et al., 2007; Pavese et al., 2004). Once the model is specified, it acts as a template that completely characterizes the search space for compatible motifs. Such a model is usually fixed by the biologist, who is willing to corroborate her hypothesis on the co-regulation of some given genes.

In the context of simple motifs, models can be fixed by the biologist in terms of Position Weighted Matrices (PWM) (Hughes et al., 2000), or IUPAC strings (Sinha and Tompa, 2003a,b), or consensus strings (Marsan and Sagot, 2000). These have been adopted by earlier approaches that analyzed the genome of simple prokaryotic organisms. However, when moving to eukaryotic transcription, things may become more complicated, and more complex motif templates have been considered in the literature (Werner, 1999; Sinha, 2002; Chen et al., 2005; Osanai et al., 2004; Tu et al., 2004). Indeed, conserved regions may consist of more than two short subsequences (in many cases, each one up to about 12 bases (Pavese et al., 2004)), and each consecutive pair of boxes might be separated by some specific gap (Werner, 1999; Sinha, 2002).

It is worth observing that, with the inclusion of “don't care” symbols in motif models, the distinction between simple and structured motifs is blurred, and constraining motif structures and/or matching functions for approximate matching is harder.

Approaches to Motif Search

In the literature outside bioinformatics, several algorithms for the discovery of frequent patterns have been proposed. As an example, the basic problem of finding frequent substrings has been deeply studied in the market-basket analysis. Here, sequences represent purchase transactions, and several algorithms to find frequent sequences have been proposed (see, for instance, Agrawal and Srikant, 1995; Zaki, 2001; Pei et al., 2001; Ayres et al., 2002). These approaches can be applied to general cases, where the alphabet is not fixed.

When dealing with the genomic domain and, in general, with the bioinformatics context, a plain adaptation of these approaches is generally unpractical (Wang et al., 2004; Ester and Zhang, 2004). For this reason, several specialized algorithms for motif search have been presented in the biological domain. These differ on several aspects, and an overview of all their typologies might be anyway incomplete.

Some authors (e.g., Brazma et al., 1998a; Das and Dai, 2007) tried to classify motif search approaches based on: (1) the underlying algorithms; (2) the kinds of derived motif; (3) the kinds of considered match. In the following, we examine these three taxonomies, one per subsection.

Classifying Motif Search Approaches Based on the Underlying Algorithms

Most literature on motif search categorizes the corresponding approaches by considering the underlying algorithm. In this case, it is possible to recognize three main categories, namely string-based, model-based, and phylogeny-based approaches. They are examined in more detail in the next subsections.

String-based approaches

String-based approaches rely on an exhaustive enumeration of potential motif candidates, followed by a counting of their occurrences. This kind of approach guarantees the exploration of the whole search space and, consequently, optimality. Obviously, they are appropriate only for short motifs. As a consequence, from a bioinformatics point of view, the kinds of subject under examination may significantly influence the possibility to adopt them. For instance, motifs in eukaryotic genomes are usually shorter than motifs in prokaryotes.

Optimized searches are achieved by applying advanced data structures, like suffix trees (Sagot, 1998), which, however, allow a perfect speedup for exact matches only.

String-based methods are also particularly suited for fixed structure motifs; in fact, when motifs have weakly constrained positions, or when their structure is not fixed, derived results may need some post-processing and refinement (Vilo *et al.*, 2000).

These methods guarantee global optimality, since they guarantee the generation and testing of all potential motifs. However, a relevant issue of them is that they may generate several irrelevant motifs; as a consequence, the validation phase is crucial, and it may become computationally expensive.

A slight variant of these approaches performs the enumeration of potential motifs actually expressed in the sequence database. This variant allows the reduction of the number of candidates. However, it may miss some motifs, when approximate matches are taken into account. As a matter of facts, it may happen that a true motif is actually not explicitly mentioned in the sequences, but it is represented by small variants of it.

A large (even if not exhaustive) variety of string-based approaches can be found in Bucher (1990), Bailey and Elkan (1995), Vilo *et al.* (2000), Van Helden *et al.* (2000), Tompa (1999), Sinha and Tompa (2000), (2003a,b), Mewes *et al.* (2002), Brzma *et al.* (1998b), Vanet *et al.* (2000), Carvalho *et al.* (2006), Pavesi *et al.* (2001), Eskin and Pevzner (2002), Pevzner and Sze (2000), Liang *et al.* (2004), and Fassetti *et al.* (2008).

Model-based approaches

Model-based approaches, also called probabilistic approaches, usually employ a representation of motif models by means of a position weight matrix (Bucher, 1990). Here, each motif position is weighed by the frequency of the corresponding symbols.

These models can be graphically represented by staking letters over each position, where the dimension of a letter is proportional to its information content in that position.

Probabilistic methods are often based on several forms of local search, such as Gibbs sampling and Expectation Maximization (EM), or on greedy algorithms that may converge to local optima. As a consequence, they cannot guarantee that the derived solution is globally optimal.

Model-based approaches are well suited to find long or loosely constrained motifs. Therefore, they can be useful for motif search in prokaryotes, where motifs are generally longer than the ones of eukaryotes.

A large (even if not exhaustive) variety of model-based approaches can be found in Hertz and Stormo (1999), Down and Hubbard, 2005, Liu (2008), Liu *et al.* (1995), (2001), Hughes *et al.* (2000), Thijs *et al.* (2002), Shida (2006), Buhler and Tompa (2002), and Kim *et al.* (1994).

Phylogeny-based approaches

Phylogeny-based approaches try to overcome the fact that classic motif search approaches consider input sequences independent from each other, i.e., they do not consider the possible phylogenetic relationships existing among input sequences. As a matter of facts, since sequence databases often contain data from closely related species, the choice of motifs to report should take this information into account.

One of the most important advantages of phylogenetic footprinting approaches is that they allow the identification of even single gene-specific motifs, if they have been conserved through sequences. However, one crucial task in these approaches is the choice of correlated sequences.

A naive method for searching phylogeny-based motifs consists in constructing a global multiple alignment of input sequences, which can be, then, used to identify conserved regions by means of well assessed tools, such as CLUSTALW (Thompson *et al.*, 1994).

However, this approach may fail in some cases; indeed, if the species are too correlated, non functional elements, along with functional ones, are conserved. On the contrary, if the sequence set is poorly correlated, it might be impossible to properly align sequences. To overcome this problem, some algorithms adapt standard motif search approaches, like Gibbs sampling, by including two important factors capable of measuring motif significance, namely over-representation and cross-species conservation. Some representative approaches belonging to this category are Carmack *et al.* (2007), Wang and Stormo (2003), Sinha *et al.* (2004), Siddharthan *et al.* (2005), Zhang *et al.* (2009, 2010), and Nettling *et al.* (2017).

Classifying Motif Search Approaches Based on the Kinds of Derived Motif

Taking this taxonomy into consideration, and based on what we have seen in Section Motifs, it is possible to distinguish approaches to extracting simple motifs from the ones to searching structured motifs.

Approaches to searching simple motifs

Simple motif extraction has been extensively studied in the literature. A former survey, which also introduces a formal framework to categorize patterns and algorithms, is presented in [Brazma et al. \(1998a\)](#). A more recent survey on this topic can be found in [Das and Dai \(2007\)](#). Among the most famous and best performing approaches in this context, we find MEME ([Bailey and Elkan, 1995](#)), CONSENSUS ([Hertz and Stormo, 1999](#)), Gibbs sampling ([Neuwald et al., 1995](#)), random projections ([Buhler and Tompa, 2002](#)) and MULTIPROFILER ([Keich and Pevzner, 2002](#)).

Approaches to searching structured motifs

When moving to structured motifs (also called composite motifs in the literature), the variety of existing approaches increases significantly. The simplest forms of these approaches are the ones for deriving “spaced dyads” (i.e., pairs of oligonucleotides at fixed distances from one another), or approaches for searching motifs composed of three boxes separated by a fixed length ([Van Helden et al., 2000](#); [Smith et al., 1990](#)). These approaches enumerate all possible patterns over the underlying alphabet, coherently with the chosen structure. Clearly, approaches like these are limited to the search of small motifs.

Some approaches for loosely structured motif extraction first derive simple motifs and then try to combine them for obtaining composite motifs. Other approaches try to obtain structured motifs directly. As an example, in [Eskin and Pevzner \(2002\)](#), an approach called MITRA is presented. It consists of two steps. The former pre-processes input data to obtain a new (bigger) input sequence by combining portions of simple motifs into virtual monads, which represent potentially structured motifs. The latter applies an exhaustive simple motif discovery algorithm to virtual monads for detecting patterns repeated significantly. Selected virtual monads are, then, decomposed back into structured patterns.

Other approaches, like SMILE ([Marsan and Sagot, 2000](#)), RISO ([Carvalho et al., 2006](#)), and L-SME ([Fassetti et al., 2008](#)), exploit efficient data structures, like suffix trees, factor trees, and other variants, for both explicitly representing structured motif candidates and efficiently counting their occurrences. In order to improve performances, [Fassetti et al. \(2008\)](#) introduces a randomized variant of the algorithm, based on sketches, which efficiently estimates the number of approximate occurrences of loosely structured patterns.

Considered motif structures may vary in several ways. In these cases, the concepts of boxes, skips, and swaps ([Marsan and Sagot, 2000](#); [Fassetti et al., 2008](#)) have been introduced as possible alternatives. However, also other classical structures, like tandem repeats or palindromes, received some interest.

Classifying Motif Search Approaches Based on the Kinds of Adopted Match

Taking this taxonomy into account, and based on what we have seen in Section Matches And Repetitions, it is possible to distinguish approaches based on exact matches from the ones adopting approximate matches. As a matter of facts, only former motif extraction approaches ([Van Helden et al., 2000](#); [Smith et al., 1990](#); [Brazma et al., 1998a,b](#); [Jonassen et al., 1995](#)), or approaches allowing arbitrary motif structures ([Wang et al., 2004](#)), consider exact matches. Indeed, since exception is the rule in biology, at least some approximation level is necessary.

The simplest approaches adopting approximate matches employ *degenerate alphabets* ([Brazma et al., 1998a](#)). These alphabets consider the fact that input symbols may be grouped in different classes, based on their meaning. For instance, aminoacids are either hydrophobic, neutral, or hydrophilic; as a consequence, they can be partitioned and mapped onto a three-symbol alphabet. A fully degenerate alphabet may include partially overlapping groups, where one symbol may be assigned to more than one class. Examples of approaches allowing degenerate alphabets can be found in [Neuwald and Green \(1994\)](#) and [Brazma et al. \(1998a,b\)](#).

More general motif search approaches adopting approximate matchings rely on some form of matching functions. One of the most common matching functions adopted by this kind of approach is the Hamming distance for its low computational cost and simplicity ([Neuwald and Green, 1994](#); [Eskin and Pevzner, 2002](#); [Marsan and Sagot, 2000](#); [Carvalho et al., 2006](#); [Fassetti et al., 2008](#)). Only few approaches consider the application of the Levenshtein distance (see, for instance, [Fassetti et al., 2008](#)), but at the price of a higher computational complexity.

Assessing Motif Relevance

Now, taking into account what we have seen in Section Motifs, given a pattern occurring in the sequence database, to determine whether it is a motif or not, it is necessary to assess its *relevance*. To carry out this task, the frequency of the pattern occurrences is clearly not enough. Indeed, there are patterns that, most probably, will be really frequent. As an extreme example, consider simple motifs composed of one symbol. Obviously, there is no surprise that all single DNA bases will be very frequent in a (portion of) genome. On the other side, a relatively high frequency of a very long pattern may be worth of deeper studies.

Unfortunately, there is still no widely accepted measure for assessing the relevance of a pattern yet, and, often, different fitness measures may result in quite different motif sets, returned by motif search approaches. Furthermore, the decision is

usually strongly dependent on some empirically chosen threshold. For all these reasons, assessing motif relevance is still an open issue.

An interesting attempt in this direction is described in [Apostolico et al. \(2003\)](#), where the authors introduce the “theory of surprise” to characterize unusual words. One of the most basic, and yet one of the most used, score functions for measuring the unexpectedness of a pattern is the z-score. This function is based on the (suitably normalized) difference between observed and expected pattern counts. Variants of the z-score differ for the normalization method and for the estimation of the number of expected patterns. For instance, this number might be obtained as an average on random strings or by a probabilistic estimation. However, counting pattern occurrences on random sequences might be computationally heavy. Other approaches are based on Expectation Maximization (EM) algorithms. In this case, motifs are incrementally enriched until to some maximal interest score is registered, and further enrichments would lead to a decrease of this score. Some recent approaches employ Markov chain models for functional motif characterization and evaluation (see, for instance, [Wang and Tapan, 2012](#)).

In [Tomba et al. \(2005\)](#), the authors use several statistic parameters (like sensitivity, specificity, etc.) to assess the performance quality of existing tools. However, in this case, some background knowledge on the real motifs, expected from the sequence database, is required. This knowledge could be based on information like the number of true/false positives, the number of motifs predicted in the right positions, etc. As a consequence, these statistics are more useful for an ex-post tool evaluation, rather than for guiding motif search. Interestingly, this analysis showed quite a poor performance of the state-of-the-art tools on real data sets. The reasons underlying this fact are presumably related to the poor estimation of the statistical relevance of returned motifs with respect to the actual biological relevance, and to the fact that motif search is actually based only on sequences.

As a final consideration about this issue, we evidence the popularity of several private and public databases, which report experimentally assessed and, in some cases, statistically predicted, motifs for transcription factor binding sites in different organisms. Some of these databases are TRANSFAC ([Matys et al., 2003](#)), JASPAR ([Sandelin et al., 2004](#); [Vlieghe et al., 2006](#)), SCPD ([Zhu and Zhang, 1999](#)), TRRD ([Kolchanov et al., 2000](#)), TRED ([Zhao et al., 2005](#)), and ABS ([Blanco et al., 2006](#)).

Closing Remarks

In this article, we have provided a presentation of algorithms for motif search. We have seen that this problem is very relevant in bioinformatics, since information encoded in biological sequences allow the identification of genetic-related diseases and resulted useful for deciphering biological mechanisms. Initially, we have defined the concepts of string, sequence, match, repetition and motif. Then, we have presented three possible taxonomies of approaches to motif search and, based on them, we have provided a description of these approaches. Finally, we have illustrated the issue of motif relevance assessment.

Research on motif discovery is moving in several directions. Several approaches are focusing on the application of existing computer science solutions to specific biological domains, such as the detection of transcription factors of specific genes. In this research area, biological insights on the analyzed organisms are strongly exploited to trim the number and quality of returned motifs. Other approaches are focusing on the reduction of the number of returned motifs; this objective is obtained by detecting closed sets of motifs (like non-redundant motifs or bases of motifs). Finally, since significant research efforts in bioinformatics are moving to the analysis of regulatory networks, a significant amount of research on motifs is shifting from the analysis of sequences to the search of motifs in networks.

Algorithms for Strings and Sequences: Pairwise Alignment

Stefano Beretta, University of Milan-Biocca, Milan, Italy

© 2019 Elsevier Inc. All rights reserved.

Introduction

The problem of aligning sequences is probably one of the classical and most important tasks in bioinformatics. In fact, in many studies one needs to compare strings or search for motifs such as, for example, nucleotide reads obtained from a sequencing process that must be aligned against a reference genome, or sequences of amino acids that must be compared to each other.

Recent advances in sequencing technologies have lead to a revolution in bioinformatics, since, with the introduction of Next-Generation Sequencing methods, a huge amount of data can be produced at a cheaper cost (Schuster, 2008). Thanks to this, it is now possible to perform new studies that were not even thinkable up to some years ago, such as the identification of organisms from a metagenomic survey (Rodrigue *et al.*, 2010; America, 2009), or the identification of structural variations present in genomes (Medvedev *et al.*, 2009; Tattini *et al.*, 2015). Although the computational problems arising from these studies require new algorithms and methods that are able to efficiently compute solutions by taking advantage of the different nature of the data, pairwise sequence alignment is still widely performed. In fact, after assembling transcripts or new genomes (e.g., from new species or from new individuals), it is important to determine the degree of similarity between two sequences, since high sequence similarity usually implies that they could have the same function or properties. For example, pairwise sequence alignment could also help in identifying the function of an unknown gene, by finding a similar gene (in terms of sequence composition) of known function.

In this work we will focus on the pairwise sequence alignment problem, in which two biological sequences are compared in order to identify their similarity. Intuitively, the process of aligning two sequences consists of lining them up, by possibly inserting spaces or gaps, while keeping the original order of the symbols, so that each symbol of one sequence is mapped to a symbol of the other sequence or to a null character or gap. More precisely, after introducing some basic notions related to this problem, we will present two types of pairwise alignments: global and local. The former alignment aims at finding the best alignment over the full length of the two input sequences, while the latter is used to identify the most similar parts (substrings) of the two sequences. We will also present two approaches, based on dynamic programming, to solve these two problems, and we will describe scoring functions used to achieve specific results in the alignment of biological sequences.

Background

In this section, we introduce the basic concepts of strings and pairwise alignment.

Let Σ be a non-empty finite set of symbols. A typical choice when dealing with nucleotide sequences is $\Sigma = \{A, C, G, T\}$. A string, $s = s_1 \dots s_n$, over an alphabet, Σ , is a sequence of symbols of Σ . We would like to point out that, although in some situations these terms are used as synonyms, in the rest of the paper we will use the term “sequence” only in the biological context, while for the mathematical and algorithmic ones we will use the term “string”.

Given a string, s , over Σ , we denote by $|s|$ the length of s , and by s_i , with $1 \leq i \leq |s|$, the symbol of s at position i . Moreover, we denote by $s_{i,j}$, with $1 \leq i < j \leq |s|$, the substring of s starting at position i and ending at position j , that is, the string $s_i \dots s_j$. We also denote by ϵ the empty string.

Consider now a symbol ‘-’, not in Σ , used to denote *gaps*, that is, ‘-’ $\notin \Sigma$. In order to define an alignment between two strings, s and t , over Σ , we consider the alphabet $\Sigma' = \Sigma \cup \{-\}$. At this point we are able to define the concept of alignment. Given two strings, s and t , over Σ , the (global) *alignment* of s and t is a pair (s', t') in which (i) s' is obtained from s by possibly inserting gaps, (ii) t' is obtained from t by possibly inserting gaps, (iii) $|s'| = |t'|$, and (iv) there is no position i , with $1 \leq i \leq |s'|$, such that both s'_i and t'_i are gaps.

As an example, consider the two strings, $s = \text{ATACAC}$ and $t = \text{AAGCGC}$, over the alphabet $\Sigma = \{A, C, G, T\}$; a possible alignment of s and t is:

$$s' = A \quad T \quad A \quad - \quad C \quad A \quad C$$
$$t' = A \quad - \quad A \quad G \quad C \quad G \quad C$$

In this example we obtained s' from s by adding a gap between the first A and C symbols (4th position), and we obtained t' from t by adding a gap between the two A symbols (2nd position). Considering this representation, in each position $i \in \{1, \dots, |s'| = |t'|\}$ of the alignment, we can find one of the following four possible situations:

- *insertion*: $s'_i = '-'$, corresponding to the fact that a gap has been inserted in the first string (position 4 of the example alignment);
- *deletion*: $t'_i = '-'$, corresponding to the fact that a gap has been inserted in the second string (position 2 of the example alignment);

- *match*: $s'_i = t'_j$, corresponding to the fact that the symbol in that position is the same in both the strings (positions 1, 3, 5, and 7 of the example alignment);
- *mismatch*: $s'_i \neq t'_j$, corresponding to the fact that the symbols in that position are different (position 6 of the example alignment).

It must be noticed that, from this definition, two input strings can always be aligned. Anyway, since the goal of pairwise alignment is to assess the similarity of the two input strings, it has to be scored. A common way to do this is to assign a value to each possible situation that can happen in a position when aligning two symbols, that is, to assign score values to insertion and deletion (gap alignments), match, and mismatch. Then, the score of the alignment is computed by summing up the values of the score at each position of the alignment. More precisely, we denote by w the *scoring function* that assigns to each possible combination of symbols in Σ' a score, that is $w : \Sigma' \times \Sigma' \rightarrow \mathbb{N}$ (or $\mathbb{Q}$, if we allow rational values).

From this point of view, it is possible to measure the *distance* or the *similarity* between the two input strings, depending on the specific values assigned by the scoring function. An example of the former type of measure is the *edit distance* in which the distance between the two strings is determined by the minimum number of edit operations required to transform the first string into the second one. On the other hand, different similarity measures can be adopted to quantify how much the two given input strings are similar. Recalling the previous example, it is possible to define a *similarity scoring function* by assigning a value 1 to match positions, and value -1 to mismatch and gap alignments, that is, to both insertions and deletions. The overall score of the alignment in the example is 1 (4 - 3). More precisely, in this case the (similarity) scoring function w is:

$$w(s'_i, t'_j) = \begin{cases} 1 & \text{if } s'_i = t'_j \wedge s'_i \neq '-' \\ -1 & \text{otherwise} \end{cases}$$

with $s'_i, t'_j \in \Sigma'$, and $1 \leq i, j \leq |s'| = |t'|$. In general, with this or any other similarity scoring function, higher values of the score will correspond to “better” alignments, i.e., shorter edit distances, and the optimal global pairwise alignment will have the highest score.

As anticipated, another possible choice for the scores of the positions is the *edit distance*, which measures the number of insertions, deletions, and substitutions required to transform one string into the other. It is interesting to notice that, when dealing with biological sequences, each edit operation corresponds to a biological operation: insertion, deletion, and mutation, respectively. A specific type of edit distance is the *Levenshtein distance*, which assigns 0 to matches, and 1 to mismatches and gap positions. In this case the scoring function modeling the edit distance w_{ed} is:

$$w_{ed}(s'_i, t'_j) = \begin{cases} 0 & \text{if } s'_i = t'_j \wedge s'_i \neq '-' \\ 1 & \text{otherwise} \end{cases}$$

with $s'_i, t'_j \in \Sigma'$, and $1 \leq i, j \leq |s'| = |t'|$. Since this is a distance measure, it corresponds to counting the number of non-matching positions, which means that the optimal alignment is the one that minimizes the score.

Obviously, there may be more than one solution, i.e., alignment, with the same optimal score.

In Section Methodologies a more detailed explanation of the *scoring function*, which assigns a score value to each possible combinations of symbols of the alphabet Σ' used in the alignment, will be provided.

Methodologies

As anticipated in Section Background, the goal of pairwise alignment of two input strings is to find the alignment having the best score. In this context, we can distinguish two type of alignments, namely *global* and *local*. In particular, the former type aligns each position of the two input strings by computing the best score that includes every character in both sequences, while the latter type aims at finding the regions of the input strings, that is, substrings, with the best match. To solve these problems, there exist different techniques, ranging from manual alignments made by inspection of the strings, to comparison using the dotplot matrix. Anyway, the most widely used techniques for the pairwise alignment, both global and local, rely on dynamic programming algorithms, in which the optimal alignment is obtained recursively by using the previously computed solutions of smaller substrings.

In the rest of this section, we will describe the *Needleman-Wunsch* algorithm (Needleman and Wunsch, 1970) which solves the global pairwise alignment problem, and the *Smith-Waterman* algorithm (Smith and Waterman, 1981), which solves the local pairwise alignment computation. Both algorithms are based on dynamic programming (Bellman, 1954). Moreover, we will also discuss different scoring functions which are commonly adopted to evaluate the alignments of biological sequences, i.e., nucleotide or protein.

Before presenting the two aforementioned algorithms, we will briefly explain the main concepts of dynamic programming, which is employed by both the methods. The idea is to recursively decompose the problem into subproblems and compute the solutions of the subproblems starting from partial solutions of smaller subproblems, computed at earlier stages. The dynamic programming technique can be applied when a solution to a problem can be obtained as a series of consecutive steps, each one working on a continuously growing subproblem. In this way, starting from the smallest subproblems, which are directly solved, subproblems are solved by combining previously computed solutions, following back the recursive decomposition. The solution of the final stage contains the overall solution.

The idea of applying this technique to the pairwise alignment problem of two input strings, s and t , is to consider the subproblems of aligning substrings, $s_{1,i}$ and $t_{1,j}$, with increasing values of i , ranging from 1 to $|s|$, and j , ranging from 1 to $|t|$. At each step, a new pair of positions, i and j , is considered, and the score $w(s_i, t_j)$ of their alignment is added to the score of the best alignment computed in the previous step. In this way, all the best alignments of two substrings ending at the last considered position can be stored in a matrix, as well as their scores. One of the key points about this dynamic programming method is that it is guaranteed to find at least one optimal alignment of the strings, s and t , for a given scoring function. On the other hand, although this technique can be used to simultaneously align several strings, it becomes quite slow, and is therefore not practical for large numbers of strings.

In the next two sections, we describe in detail the algorithmic procedures for the computation of the optimal global and local pairwise alignments. In this presentation, we adopt the scoring function w introduced in Section Background. More precisely, we define the following scoring function:

$$w(s'_i, t'_j) = \begin{cases} 1 & \text{if } s'_i = t'_j \wedge s'_i \neq '-' \quad (\text{Match}) \\ -1 & \text{if } s'_i \neq t'_j \wedge s'_i \neq '-' \wedge t'_j \neq '-' \quad (\text{Mismatch}) \\ -1 & \text{if } s'_i = '-' \vee t'_j = '-' \quad (\text{Gap}) \end{cases}$$

with $s'_i, t'_j \in \Sigma'$, and $1 \leq i, j \leq |s'| = |t'|$. With this similarity scoring function, the optimal alignment has the highest score and, consequently, both global and local algorithmic procedures maximize it.

Global Alignment

In this section we will describe the dynamic programming algorithm proposed by Needleman and Wunsch to solve the problem of computing an optimal global alignment between two strings (Needleman and Wunsch, 1970). Anyway, although we refer to the algorithm described in the rest of this section as that of Needleman and Wunsch, this is a bit imprecise. In fact, the first dynamic programming algorithm to solve the global pairwise alignment was introduced by Needleman and Wunsch in 1970 (having complexity $O(n^3)$ in time, although an efficient implementation can achieve an $O(n^2)$ in time), but the one described here is the one proposed later by Sellers (1974). This algorithm, which is also based on dynamic programming, requires $O(n^2)$ time, and uses a linear model for gap penalties (see later).

Let s and t be two strings over the alphabet, Σ , such that $|s| = n$ and $|t| = m$. The idea of the algorithm is to compute the optimal alignments of the prefixes of s and t , and to store the score in a matrix, M , having size $(n + 1) \times (m + 1)$, in which the '+' 1' is used to represent the initial empty substring ϵ . More precisely, $M[i, j]$ represents the score of an optimal alignment of two substrings $s_{1,i} = s_{\{1\} \dots s_{\{i\}}}$ and $t_{1,j} = t_{\{1\} \dots t_{\{j\}}}$. The dynamic programming algorithm computes $M[i, j]$ for i ranging from 0 (empty prefix) to n , and j ranging from 0 to m . At the end of the procedure, $M[n, m]$ is the score of the optimal global alignment of s and t .

Now, let us define the initialization of the dynamic programming, that is, the score of aligning the empty prefixes of the strings. More precisely, we start by setting $M[0, 0] = 0$, corresponding to the score of aligning two empty prefixes ϵ . Then, since we adopt a length-dependent model for gap penalties (Sellers, 1974), for every $i \in \{1, \dots, n\}$, set $M[i, 0] = i \cdot w(s_i, '-')$, corresponding to the score of aligning a prefix of s having length i , that is $s_{1,i}$, with the empty string ϵ . The same applies also for $j \in \{1, \dots, m\}$ for which we set $M[0, j] = j \cdot w('-', t_j)$, corresponding to the score of aligning a prefix of t having length j , that is $t_{1,j}$, with the empty string ϵ .

Now, it is possible to describe the recurrence. The idea, when considering the cell $M[i, j]$ of the matrix, which corresponds to the score of the optimal alignment of the prefixes $s_{1,i}$ and $t_{1,j}$, is that we take advantage of the previously computed scores for $i-1$ and $j-1$. Since, by definition, the goal is to maximize the final alignment score, we select the maximum score value among that of the alignments of the three possible prefixes of $s_{1,i}$ and $t_{1,j}$. The score of the alignment of the prefixes $s_{1,i}$ and $t_{1,j}$ is computed as the maximum of the following three cases:

- (1) s_i and t_j are aligned, and the score is that of the alignment of prefixes $s_{1,i-1}$ and $t_{1,j-1}$ plus the score $w(s_i, t_j)$ which is positive for a match and negative for a mismatch;
- (2) there is a deletion in t ; s_i is therefore aligned with a gap '-'. The score is that of the alignment of prefixes $s_{1,i-1}$ and $t_{1,j}$ plus the score of the gap alignment $w(s_i, '-')$;
- (3) there is an insertion in t ; t_j is aligned with a gap '-'. The score is that of the alignment of prefixes $s_{1,i}$ and $t_{1,j-1}$ plus the score of the gap alignment $w('-', t_j)$.

These cases are formalized in the following equation:

$$M[i, j] = \max \begin{cases} M[i-1, j-1] + w(s_i, t_j) & (1) \\ M[i-1, j] + w(s_i, '-') & (2) \\ M[i, j-1] + w('-', t_j) & (3) \end{cases}$$

for $i \in \{2, \dots, n\}$ and $j \in \{2, \dots, m\}$. Fig. 1 offers a graphical representation of the general case of the dynamic programming recurrence to compute the score $M[i, j]$ starting from the previously computed scores.

Finally, the score $Score_{OPT}$ of the optimal alignment of the two input strings s and t is in the cell $M[n, m]$:

$$Score_{OPT} = M[n, m]$$

Fig. 1 Graphical representation of the computation of $M[i, j]$ in the matrix M using a linear gap penalties model (Sellers, 1974). Here, the 3 previously computed values on which the recurrence is based are highlighted, namely $M[i-1, j-1]$, $M[i-1, j]$, and $M[i, j-1]$. Labels on the arrows report the additional score that is added, corresponding to the pair of aligned symbols.

Fig. 2 Example of the computation of optimal alignment matrices for the two input strings $s=ATACAC$ and $t=AAGCGC$. The left matrix represents the score of the optimal (maximum) alignment, while the right matrix contains the arrows to keep track of the best choice done to obtain the optimal score. The grey path corresponds to the optimal final alignment. In both the matrices, instead of reporting the values of $i \in \{0, \dots, 6\}$ and $j \in \{0, \dots, 6\}$ as row and column names, respectively, we used the corresponding symbols of the strings, $\{\epsilon, s_1, \dots, s_6\}$ and $\{\epsilon, t_1, \dots, t_6\}$, respectively.

Anyway, in order to reconstruct the optimal alignment (or alignments if there is more than one), it is necessary to keep track, for each pair of symbols at positions i and j , from which of the three aforementioned cases was obtained the value $M[i, j]$ during the dynamic programming. More precisely, since to compute $M[i, j]$ we select the maximum value among the 3 possible cases of the dynamic programming recurrence, in order to reconstruct the optimal alignment we have to compute from which value we obtained the maximum score $M[i, j]$ among $M[i-1, j-1]$, $M[i-1, j]$, and $M[i, j-1]$ (see Fig. 1). A possible way to represent this choice is to use arrows pointing to the corresponding matrix cell so that, once the matrix is completed, a path can be traced from the cell with the optimal value $Score_{OPT}$ (i.e., $M[n, m]$) to $M[0, 0]$, and the alignment reconstructed from the pairs of letters aligned at each step. This reconstruction process is usually called *traceback*. In fact, there is a pair of symbols corresponding to each possible arrow at a given position i, j of the matrix:

- ↖ corresponds to the alignment of symbols s_i and t_j ;
- ↑ corresponds to the alignment of symbols s_i and '-';
- ← corresponds to the alignment of symbols '-' and t_j .

The two matrices in Fig. 2 show the scores and the corresponding arrows for the computation of the optimal alignment of the two input strings used as an example in Section Background: $s=ATACAC$ and $t=AAGCGC$. By slightly abusing the notation, the row/column indices can be used as the symbols of the input string s/t , instead of the positions $i \in \{0, \dots, 6\}$ and $j \in \{0, \dots, 6\}$. Following the path in the right matrix of Fig. 2 we can reconstruct an optimal alignment having score equal to 1:

$$s' = A \quad T \quad A \quad - \quad C \quad A \quad C$$

$$t' = A \quad - \quad A \quad G \quad C \quad G \quad C$$

We would like to point out that, for ease of exposition, in the example in Fig. 2 only a single arrow for each cell of the matrix is shown, whereas, in reality, an equal optimal score can frequently be obtained from multiple "directions". This is due to the fact

that there could be multiple alignments of the two input strings having the same optimal score, $Score_{OPT}$. For this reason, if it is necessary to reconstruct all the optimal alignments of two given strings, for each cell, all the possible optimal choices should be stored. Moreover, the traceback step used to reconstruct the optimal alignment should explore all the possible paths (not just a single one) from $M[n, m]$ to $M[0, 0]$.

Local Alignment

In this section, we will describe the algorithm proposed by Smith and Waterman, which is used to solve the problem of computing the optimal local alignment of two input strings (Smith and Waterman, 1981). The goal of this procedure is to find the substrings of the input strings that are the most similar, with respect to a given scoring function, which usually represents a similarity measure (like the one used in Section Global Alignment to describe the global alignment).

The Smith–Waterman algorithm is based on a dynamic programming recurrence similar to that used to find the global pairwise alignment, and follows the same idea: compute a matrix with the optimal scores of the alignments of the prefixes of the input strings, keeping track of the previous optimal partial alignments, and at the end follow a traceback path to reconstruct an optimal alignment.

Formally, given two input strings, s and t , having lengths n and m , respectively, we compute a $(n + 1) \times (m + 1)$ matrix M , in which $M[i, j]$, with $i \in \{0, \dots, n\}$ and $j \in \{0, \dots, m\}$, represents the optimal (maximum) score of a local alignment between the substrings $s_{1,i}$ and $t_{1,j}$. Here, the interpretation of the matrix values is slightly different with respect to that of the global pairwise alignment: $M[i, j]$ represents the score of the best alignment of a suffix of $s_{1,i}$ and a suffix of $t_{1,j}$. In the local pairwise alignment matrix, the first row and the first column, i.e., those with index 0, are set to 0, since there is no penalty in introducing gaps. Moreover, as anticipated, for each cell of the matrix we store the path taken to obtain the maximum score value (i.e., through an arrow to the corresponding cell) in order to reconstruct the best local alignment.

The recurrence starts by setting the first row and the first column of the matrix M with 0, that is, $M[0, j] = 0$, with $j \in \{0, \dots, m\}$, and $M[i, 0] = 0$, with $i \in \{0, \dots, n\}$. Now, the recursive case of the recurrence, is:

$$M[i, j] = \max \begin{cases} M[i-1, j-1] + w(s_i, t_j) \\ M[i-1, j] + w(s_i, '-') \\ M[i, j-1] + w('-', t_j) \\ 0 \end{cases}$$

for $i \in \{1, \dots, n\}$ and $j \in \{1, \dots, m\}$.

Notice that, while an alignment can be produced for any scoring system, if the average score for comparing the letters is not below zero or, more in general, for all positive scoring systems, it will result in a global alignment (and not in a local one).

and for an all positive scoring system

The value 0 at position (i, j) , i.e., $M[i, j] = 0$, indicates that a new alignment starts at this position. In fact, if the score of the best alignment up to (i, j) is negative, then it is better to start a new one. Differently from the global pairwise alignment procedure described before, all the negative scores are replaced by 0 s in the matrix M .

Finally, the score of the optimal local pairwise alignment between s and t can be found by searching for the highest value in the matrix M :

$$Score_{OPT} = \max\{M[i, j] : 1 \leq i \leq n, 1 \leq j \leq m\}$$

After that, similarly to the global alignment procedure, in order to reconstruct a local alignment having optimal score, it is necessary to follow the traceback path, from the matrix cell of M having score $Score_{OPT}$ up to a cell having score equal to 0.

The matrices in Fig. 3 show an example of optimal local alignment for the two input strings $s = ACTAAG$ and $t = CTCAAT$ w.r.t. the scoring function introduced at the beginning of Section Methodologies. More precisely, the left matrix reports the score values obtained with the dynamic programming recurrence, while the matrix on the right shows the arrows corresponding to the choices made, that is, the cells from which the values have been obtained. In this latter matrix, we use a dot (i.e., $\cdot$) for those cells with a 0 score obtained through the last case of the dynamic programming recurrence.

On the other hand, as in the example of the global pairwise alignment shown in Section Global Alignment, only one arrow for each cell is shown, following the order shown in the definition of the recurrence, when there is more than one possible choice. Finally, the grey path corresponds to the optimal local alignment having $Score_{OPT} = 3$:

$$\begin{aligned} s' &= C & T & - & A & A \\ t' &= C & T & C & A & A \end{aligned}$$

Extension to Affine Gap Model

Now, let us analyze the introduction of gap symbols in the alignment. Both the algorithms described in Section Global Alignment and Section Local Alignment use a linear gap model to assign a score to the alignment of a symbol in the alphabet Σ with the gap '-'. This usually consists of a negative score associated with a gap being dependent on the number of successive gap characters.

$s \backslash t$	ϵ	C	T	C	A	A	T
ϵ	0	0	0	0	0	0	0
A	0	0	0	0	1	1	0
C	0	1	0	1	0	0	0

Fig. 3 Example of the computation of optimal local alignment matrices for the two input strings $s = ACTAAG$ and $t = CTCAAT$. The left matrix represents the score of the optimal (maximum) alignment, while the right matrix contains the arrows to keep track of the best choice done to obtain the optimal score. The grey path corresponds to the optimal local final alignment. In both the matrices, instead of reporting the values of $i \in \{0, \dots, 6\}$ and $j \in \{0, \dots, 6\}$ as row and column names, respectively, we used the corresponding symbols of the strings, $\{\epsilon, s_1, \dots, s_6\}$ and $\{\epsilon, t_1, \dots, t_6\}$, respectively.

More precisely, in this *length-dependent* gap model, the score of introducing a sequence of k consecutive gap symbols in an aligned string s is $k \cdot w(t_j, '-')$, with $1 \leq j \leq m$, that is k times the score of aligning a symbol t_j of t with a gap (Sellers, 1974).

Anyway, in many biological analyses (but also in other research fields) having k consecutive gaps is preferable to having k gaps scattered along the strings in different positions. For this reason, a different gap model, which distinguishes between the score for opening the gap (length independent score) and the cost proportional to the gap length, was introduced by Gotoh (1982). This model, also known as the *affine* gap cost model, penalizes alignments with many scattered gap positions more than alignments with more consecutive ones.

Now, given a gap opening cost h , and a gap proportional cost similar to that used in Section Global Alignment and Section Local Alignment, the dynamic programming recursion to compute the global pairwise alignment can be modified as follows:

$$M[i, j] = \max \begin{cases} M[i-1, j-1] + w(s_i, t_j) \\ I_s[i-1, j-1] + w(s_i, t_j) \\ I_t[i-1, j-1] + w(s_i, t_j) \end{cases}$$

$$I_s[i, j] = \max \begin{cases} M[i-1, j] + h + w(s_i, '-') \\ I_s[i-1, j-1] + w(s_i, '-')$$

$$I_t[i, j] = \max \begin{cases} M[i, j-1] + h + w('-', t_j) \\ I_t[i, j-1] + w('-', t_j) \end{cases}$$

for $i \in \{1, \dots, n\}$ and $j \in \{1, \dots, m\}$. The matrices are initialized by setting:

- $M[0, 0] = 0$;
- $I_s[i, 0] = h + i \cdot w(s_i, '-')$, with $i \in \{1, \dots, n\}$;
- $I_t[0, j] = h + j \cdot w('-', t_j)$, with $j \in \{1, \dots, m\}$;
- all the other cells in the first rows and first columns of matrices M , I_s , and I_t to $-\infty$.

The additional matrices I_s and I_t are used to deal with the introduction of gaps in the alignment, to distinguish between the case in which a new gap is opened and the case in which it is extended.

Notice that the Smith-Waterman dynamic programming recurrence can be modified in the same way to adopt the affine gap model. Anyway, in both cases, the time complexity of the two algorithms still remains $O(n^2)$.

Scoring Functions

In this section we briefly discuss different scoring functions that are used in real case studies to perform pairwise alignments, especially when dealing with nucleotide and protein sequences. More precisely, another way to represent a scoring function $w : \Sigma' \times \Sigma' \rightarrow \mathbb{N}$ which assigns a value to each possible alignment of two symbols, is through a *scoring matrix*, that is a matrix having size $|\Sigma'| \times |\Sigma'|$. In this way, to each possible pair of symbols of $\Sigma' (= \Sigma \cup \{-'\})$ is assigned a numerical value corresponding to the score for aligning the corresponding symbols. This representation provides an easy way to assign different scores to the alignments of different symbols. This is useful especially when dealing with protein alignments (but also with nucleotide), in which the

different pairs of amino acids have different degrees of chemical similarity. For this reason it is important to choose a scoring function that reflects biological observations when aligning protein sequences.

For this purpose, a set of scoring matrices has been designed to model the fact that some pairs of symbols are more probable than others in related sequences, by encoding the log-odd scores of amino acid mutations. In fact, although different types of scoring matrices have been proposed, such as those based on the similarity in terms of chemical properties, the ones obtained from empirical observations have shown to perform better than the others. The two most widely used matrices adopted for the pairwise alignment of protein sequences are Percent Accepted Mutation (PAM) (Dayhoff and Schwartz, 1978) and BLOSUM (Henikoff and Henikoff, 1992) matrices.

The former, i.e., the PAM matrices, have been computed by observing point mutation rates of amino acids in closely related proteins, with known phylogenies. The scores in the PAM1 matrix have been obtained by aligning closely related protein sequences, and estimate the expected rate of substitution if 1% of amino acids undergo substitutions. Starting from the PAM1 matrix, the PAM2 matrix is created by assuming an additional 1% of changes of the amino acids and, mathematically, this is done by multiplying the PAM1 matrix by itself. In general, this process can be repeated n time in order to obtain the PAM n matrix. The most widely used PAM matrices are PAM30, PAM70, PAM120, and PAM250. It must be pointed out that the scores of a PAM matrix are the logarithms (usually base 2) of the rate, averaged over the forward and backward substitution, and normalized to the rate of seeing a given amino acid (*log-odds scores*).

The other set of scoring matrices commonly used in the pairwise alignment of biological sequences are the BLOSUM matrices (Henikoff and Henikoff, 1992), which are based on the blocks database. These matrices consist of the logarithms (usually base 2) of the relative substitution frequencies of the aligned blocks from different protein families, representing a variety of organisms (*log-odds scores*). As for the PAM matrices, different BLOSUM matrices have been computed, each one having a different threshold of minimum similarity among the sequences of the organisms. More precisely, the BLOSUM N matrix is built by considering sequences having more than the $N\%$ of similarity as corresponding to a single sequence, thereby downweighting the information from highly similar sequences. One of the most used matrix is the BLOSUM62 matrix, which is built by clustering together and downweighting sequences with more than the 62% of identity (Styczynski *et al.*, 2008).

Conclusions

In bioinformatics, one of the most classical problems is the alignment of two biological sequences, which is usually performed in order to assess similarities of DNA, RNA, or protein strings. Due to its importance, this problem has been thoroughly studied and many different variants proposed in literature. The two most important variants are global and local pairwise alignment. To solve these type of problems, the two most famous approaches are those proposed by Needleman and Wunsch, and by Smith and Waterman to compute optimal global and local pairwise alignment, respectively. Both techniques are based on dynamic programming algorithms, which find the optimal score of the pairwise alignment, with respect to a given scoring function, and also reconstruct an optimal alignment of the two input strings. In discussing the two recurrences on which the two algorithms are based, we provided also some an example for showing their functioning.

In this work, in addition to the linear gap model adopted in both the dynamic programming algorithms for solving the global and local pairwise alignments, we also discussed the affine gap model. Finally, we discussed some variants of the scoring function that are usually adopted in real case studies, in order to deal with biological sequences.

Further Reading

For a more detailed discussion on the pairwise alignment problem, we refer the reader to (Jones and Pevzner, 2004), to (Gusfield, 1997), and to (Setubal and Meidanis, 1997). These books provide a description of different methods for solving global and local pairwise alignment problems, in addition to the one presented in this work, and also give an extensive explanation of different scoring functions adopted for the alignment of biological sequences. In these books, heuristic methods for solving the aforementioned problems are discussed in detail. Moreover, a detailed analysis of gap penalties and different scoring functions is present in the aforementioned books.

Algorithms for Strings and Sequences: Multiple Alignment

Pietro H Guzzi, University "Magna Graecia" of Catanzaro, Catanzaro, Italy

Introduction

In computational biology and bioinformatics, the term sequence alignment refers to the identification of regions of similarity among the sequence of gene and gene products. Similarity may be a consequence of evolution, therefore alignment is a way to infer the impact of the evolution and the evolutionary relationship among sequences.

Sequence alignment algorithms fall into two main classes considering the number of aligned sequences: pairwise and multiple. A multiple sequence alignment (MSA) is a sequence alignment that receives as input three or more sequences and produces as output the analysis of similarity among the sequences. Sequence alignment algorithms are usually based on the concept of edit distances, i.e. how many changes are needed to transform one sequence into another one. The output of MSA is generally matrices for a visual depiction of the alignment to enhance the similarity and the differences. Differences or point mutations (single amino acid or nucleotide changes) that appear as different characters in a single alignment column, and insertion or deletion mutations (indels or gaps) that appear as hyphens in one or more of the sequences in the alignment.

From a computational point of view the multiple sequence alignment can be computationally expensive, and in general time-consuming, therefore multiple sequence alignment programs use heuristic methods rather than global optimization (Thompson *et al.*, 2002).

Multiple Sequence Alignment Algorithms

Initially, MSAs used dynamic programming to identify the best optimal alignment, extending the pairwise approaches. The optimization strategy was based on two main parameters: a penalty for differences (gap penalty) and a matrix used for assignment scores for the changes.

Given n sequences, the naive algorithm is based on the construction of an n -dimensional matrix extending the two-dimensional matrix used in pairwise algorithms. Consequently, the search space grows exponentially. It has been demonstrated that dynamic programming, in this case, give an NP-complete problem. The Carrillo-Lipman algorithm (Carrillo and Lipman, 1988) represents an evolution of this simple scheme yielding a reduction of the complexity preserving the global optimum (Lipman *et al.*, 1989).

The computational complexity of the problem caused the introduction of approximate algorithms based on a heuristic.

A big class of heuristic algorithms is usually defined to as progressive alignment (also known as hierarchical or tree-based methods). They are based on the progressive technique developed by Paulien Hogeweg and Ben Hesper (Hogeweg and Hesper, 1984). Each progressive alignment is based on two steps: (i) initially all the pairwise alignment are calculated, and the relationships are represented as a tree (guide tree), (ii) the building of MSA by adding the sequences sequentially to the growing MSA according to the guide tree. The initial guide tree is calculated using clustering methods, such as neighbour-joining or UPGMA. Examples of progressive alignments are the Clustal series and T-Coffee.

Consensus methods try to find the optimal MSA given multiple different alignments of the same set of sequences. Examples of consensus methods are M-COFFEE and MergeAlign. M-COFFEE uses multiple sequence alignments generated by seven different methods that are integrated to build consensus alignments. MergeAlign extends the previous approach by accepting as input a variable number of input alignments generated using different models of sequence evolution or different methods of multiple sequence alignment.

Iterative methods build a MSA by iteratively realigning the initial sequences as well as adding new sequences to the growing MSA. Examples of iterative methods are the software package PRRN/PRRP and DIALIGN.

Tools for Multiple Sequence Alignment

The Clustal is a series of computer programs used for multiple sequence alignment. Clustal series is composed by:

- Clustal: The original software for progressive alignment.
- ClustalW and ClustalX that are respectively a command line interface and the graphical user interface.
- Clustal ω (Omega): The current standard version that is available via a web interface.

To perform an alignment using ClustalW, you may select the sequences or alignment you wish to align. Then you have to choose the available options: Cost Matrix (the desired cost matrix for the alignment); Gap open cost and Gap extend cost; Free end gaps; Preserve original sequence order. After entering the desired options click OK and ClustalW will be called to align the selected sequences or alignment. Once complete, a new alignment document will be generated with the result as detailed previously.

Introduction

After the Human Genome Project, which had the goal of sequencing the whole genomes of various organisms, the focus of research moved towards proteomics. Proteins are long biomolecules which are responsible of the vast majority of the complex signaling and chemical interactions in the cell. The role of a protein is mainly due to its geometrical shape which determines which of its amino acids, also known as residues, are exposed towards other molecules and also the chemical potential of its binding sites, hence all of its properties. The role a protein has in the cell is often referred to as its function. Protein function prediction is also a very active research field in which the protein shape is a key information for achieving good prediction results. Many scientific expertises are involved in protein structure prediction research, among which: mathematicians, Chemists, Medicinal Chemists, Physicians, Biologists, Physicists and Computer Scientists.

The scientific community working on protein structure prediction formulated this problem as the Protein Folding Problem (PFP), which tries to give an answer to the following question: which are the rules behind protein folding? More precisely, PFP has the main goal to understand which is the function to map a sequence of amino acid (primary sequence) into the spatial description of all atoms in the molecule (tertiary structure). Proteins are described by a number of such structures, as we will see in the following.

Proteins are long molecules composed of a chain of amino acids. Each amino acid derives from a triplet on a coding portion of the genome. The ribosome (another protein) reads such triplets of bases from a messenger RNA (mRNA) and creates the chain of amino acids of the protein, according to the central dogma of biology (see [Crick, 1970](#)). While the polypeptide chain of a protein is being forming, the interactions among amino acids bend it in order to reach the structure with the lowest conformational energy. Such a process is called protein folding. The central dogma states that all information flows from the nucleus (i.e., DNA) towards the proteome and not vice versa. This implies that the sequence of amino acids translated from the genome implies its shape because of the function that has to be implemented in the cell. However, as we will see in the next section, exceptions to this rule have been observed in nature. In particular, under varying environmental conditions, the same protein folds into different shapes.

Protein structures can be determined experimentally, for instance by using X-ray crystallography or NMR (Nuclear Magnetic Resonance), but such experiments are both time consuming and extremely costly. Computer-based approaches are able to define statistical and mathematical models which can predict protein structures in high throughput pipelines, thus enabling investigations not feasible with classical approaches, such as: (i) Genome-wide studies, in which all proteins of a genome are transcribed *in silico* (ii) screenings of large datasets of molecules, used in chemoinformatics investigations, (iii) ligand docking screenings, with which researchers try to find the best target for a particular ligand, (iv) unknown target identification and classification, in which a novel protein is assigned to a class or labeled with its domains. Furthermore, structure predictions can be used to create vast curated and annotated repositories of molecules and their properties, which can be integrated with other existing data sources to extract new knowledge, explain and interpret data. Such an integration with ontologies and reasoning techniques could hopefully help in finding appropriate answers to unsolved biological and clinical problems.

Background

PFP has been proposed almost 50 years ago and it can be stated as three main questions: (i) What is the mechanism responsible for the folding of the linear sequence of amino acids composing a protein, (ii) how can proteins fold so fast and (iii) is there a way to create computer programs able to guess the 3D shape of a protein sequence will have in its folded spatial conformation ([Dill and MacCallum, 2012](#)). In nature folding is a spontaneous process driven by chemical bonds created among amino acids along the polypeptide chain of the protein. The folding process starts while the protein is being translated from the genetic code contained in messenger RNA filaments read by the ribosome.

One of the main online database containing resolved protein molecules is the Protein Data Bank (PDB), ([Berman et al., 2000](#)). The repository has been created in 1971 and originally contained as few as seven structures. This number has significantly increased over the years towards many thousands structures, mainly resolved with both X-ray crystallography and NMR. Each structure is stored in a dedicated file together with annotations about the authors, the publications describing the experiment and the list of atoms, coordinates and chemical properties of the entry. There currently exist 126,000,000 + identified protein primary sequences in the Uniprot database ([UniProt Consortium, 2016](#)) but just ~ 125,000 of them (less than one every a thousand) have an experimentally resolved 3D structure stored in the PDB Database, and the gap is rapidly widening over time. However,

according to the PDBSelect25 database, by only considering sequences being significantly different from each, i.e., having a mutual sequence identity lower than 25%, we obtain as low as ~ 4600 structures (Griep and Hobohm, 2009). This suggests that the effort of designing and implementing software systems able to perform genome-wide protein sequence structure prediction is still relevant and useful for the research community. Among the other online protein data sources, the Structural Classification of Proteins (SCOP) database contains information about evolutionary relationships among proteins and the principles that are behind their 3D structure (Reddy and Bourne, 2003). It also provides correlations with atoms coordinates resources, rendered images of the structure, sequence data and literature references.

Predicting atoms locations with high precision can be achieved by using computer based methods which: (i) Approximate the Schrödinger equation to capture chemical potentials for molecular orbitals or are based on the laws of physics to simulate forces among atoms (ii) learn from online databases containing known protein structures (e.g., the PDB), what are the statistical properties of similar sequences and create models for local (short peptides) and global (whole protein sequences) prediction. The former refers to methods based on Density Functional Theory (DFT) and on Molecular Dynamics (MD). The latter attains a large number algorithms and software tools, the vast majority of which have been created around the CASP (Critical Assessment of protein Structure Prediction) experiment research community (Moult *et al.*, 2014). We will give more details about these approaches and techniques in Section “Systems and/or Applications”.

The central dogma of molecular biology states that information flows from the coding portion of the genome towards the proteome and this flow is irreversible. Hence the protein structure is implied by the genetic information stored in the DNA/RNA and, since recently, such a structure was believed unique. However, experimental evidence of violations of such a rule has been found in the so-called metamorphic proteins (Murzin, 2008; Koonin, 2012). For these molecules, it has been noted that cell environmental factors (e.g., pH) can induce different protein structural rearrangements, even if it is still not clear if their shape can change again after the protein has folded in its first shape.

The process of genomic information translation into proteins starts once the mature messenger RNA exits from the nucleus and it is intercepted by a ribosome, a specialized protein molecule which associates an amino acid to each triplet of genes read from the mRNA sequence. Each amino acid attaches to the previous one forming a long chain which folds into a well-defined 3D structure. For the last 50 years Protein Folding Problem (PFP) has been one of the main driving forces for the investigation on tertiary structure prediction. The goal of PFP is to find the rules behind the folding of the amino acid chain of proteins. Such a function is thought to be directly implied by the primary structure of the protein, i.e., by the sequence of its amino acids.

A lot of recurrent patterns can be identified in a protein, which have been organized in well-known structures: (i) The primary structure, which is the sequence of its amino acids, (ii) the secondary structure, which stores the locations of highly organized substructures along the chain, such as alpha-helices and beta-sheets, (iii) the tertiary structure, which defines the coordinates of each atom constituting the protein and (iv) the quaternary structure, which takes into account how two or more proteins of the same kind pack together to form a complex. At the chemical level, protein molecules are long polypeptide chains in which the alpha-carbon atoms of adjacent amino acids are bond through by a covalent bond, called peptide bond.

Protein function is how a protein interacts with other molecules in the cell environment and is a direct consequence of the three-dimensional structure. There exist proteins which contribute in various roles in the cell, some of which are: (i) Catalysis of chemical reactions, where they contribute to accelerate some reactions, (ii) transport of nutrients or drugs, where their chemical shape or binding site is useful to host other molecules, (iii) mechanical functions, where their shape offers physical resistance to external forces, as for instance in hair or where they are used to achieve mechanical tasks such as the ribosome, the motor proteins or the flagellum of *Escherichia coli*, (iv) transmission and exchange of signals, where they help executing complex tasks in the cell through biochemical signaling described in cellular pathways.

Systems and/or Applications

Exact methods are widely used to precisely determine the 3D structure of protein molecules, the most used of which are NMR and X-ray crystallography. Both technologies are both costly and time consuming. The former limits the number of molecules which can be resolved with a certain budget. The latter is a compelling constraint when the number of molecules to be resolved is large.

NMR spectroscopy and X-ray crystallography are two of the most important techniques for gaining insight about the conformation of proteins. NMR spectroscopy elucidates the atomic structure of macromolecules in solution, in case of highly concentrated solutions (~ 1 mM, or 15 mg ml^{-1} for a 15-kd protein). This technique depends on certain atomic nuclei intrinsic magnetic properties. Only a limited number of isotopes display the well known property, called spin.

On the other hand, X-ray crystallography provides the finest visualization of protein structure currently available. This technique identifies the precise three-dimensional positions of most atoms in a protein molecule. The use of X-rays provides the best resolution because the wavelength of X-rays is in the same range of a covalent bond length. The three components in an X-ray crystallographic analysis are a protein crystal to be obtained, a source of X-rays, and a detector (Berg *et al.*, 2002).

In the last 30 years, Density Functional Theory (DFT) allowed great advances at the interface between Physical Chemistry and Life Science topics (Mardirossian and Head-Gordon, 2017; Medvedev *et al.*, 2017). The origin of DFT success both in academia and in industrial applications is its exact approach to the problem of electronic structure theory. According to the Born-Oppenheimer approximation, the electronic energy, $E_e[\rho(\mathbf{r})]$, can be expressed as a functional of the electron density.

$$E_e[\rho(\mathbf{r})] = T[\rho(\mathbf{r})] + V_{en}[\rho(\mathbf{r})] + J[\rho(\mathbf{r})] + Q[\rho(\mathbf{r})] \quad (1)$$

In Eq. (1), $T[\rho(\mathbf{r})]$ represents the electronic kinetic energy, $V_{en}[\rho(\mathbf{r})]$ the nuclear-electron attraction energy, $J[\rho(\mathbf{r})]$ the classical electron-electron repulsion energy, and $Q[\rho(\mathbf{r})]$ the quantum electron-electron interaction energy. The second and third terms in Eq. (1) can be evaluated by Eqs. (2) and (3), respectively.

$$V_{en}[\rho(\mathbf{r})] = - \sum_{A=1}^M \int \frac{Z_A}{|\mathbf{r} - \mathbf{R}_A|} \rho(\mathbf{r}) d\mathbf{r} \quad (2)$$

$$J[\rho(\mathbf{r})] = \frac{1}{2} \int \int \frac{\rho(\mathbf{r}_1)\rho(\mathbf{r}_2)}{r_{12}} d\mathbf{r}_1 d\mathbf{r}_2 \quad (3)$$

DFT aims to develop accurate approximate functionals for $T[\rho(\mathbf{r})]$ and $Q[\rho(\mathbf{r})]$. Particular attention should be devoted to the accurate expression of the kinetic energy contribution, the most significant unknown term. DFT has given reliable results in almost every field of science, i.e., the prediction of chemical reactions and their rate-determining step to design better catalysts (Rondinelli *et al.*, 2006, 2007; Di Tommaso *et al.*, 2007; Chiodo *et al.*, 2008; Rondinelli *et al.*, 2008), the elucidation of molecular activity from natural compounds to novel generation drugs (Leopoldini *et al.*, 2010; Botta *et al.*, 2011), the investigation of microscopic features of new materials and the study of enzyme structure, function and dynamics.

Beside the quest for more accurate functionals in order to improve the accuracy of molecular energy and structure data, DFT applications are limited by the size of the chemical systems under investigations. If it is common to model the active site of an enzyme by considering the amino acids involved in the mechanism of catalysis, taking in consideration the whole protein would be prohibitive. Density functional theory, using approximate exchange-correlation functionals, allows successful application of quantum mechanics to a wide range of problems in chemistry at a fraction of the computational requirements needed by traditional Hartree-Fock theory methods. However, DFT approach is still too computationally expensive for common biological macromolecular systems involving thousands of atoms (Qu *et al.*, 2013).

The previously described approaches can give high resolution structures but show a low efficiency when applied to protein molecules, which are huge complex molecules. In fact, in the context of PFP, even computational approaches, which have been studied theoretically in order to find limitation for the implemented algorithms, have shown to be intractable. In Hart and Istrail (1997), the authors show how, even a simplified version of the PFP problem, where the α -carbon atoms of the protein are mapped on the nodes of a lattice, used to discretize the conformational space, the folding problem is NP-hard. In Berger and Leighton (1998), authors analyze that the hydrophobic-hydrophilic (HP) model, one of the most popular biophysical models used for protein folding. The HP model abstracts the hydrophobic interactions by labeling amino acids as hydrophobic (H for nonpolar) and hydrophilic (P for polar). In such a model, chains of amino acids are considered as self-avoiding walks on a 3D cubic lattice, where an optimal conformation maximizes the number of adjacencies between H's. The authors show that the protein folding problem, under the HP model on the cubic lattice, is NP-complete.

A predictor is a software system that, given the primary structure of a protein as the input, returns an estimated secondary or tertiary structure as the output. The output structure yielded by a predictor is called its prediction. Prediction methods are designed to imitate the protein folding process and combine different information (e.g., evolutionary, energetic, chemical) and/or predictions (e.g., secondary structure, contact maps) in order to guess the protein conformation (Palopoli *et al.*, 2013). We will now describe the workflow of a typical computational approach which tries to approximate a solution for the PFP problem. Computational approaches trying to predict the protein structure use the primary sequence as the input and then a set of intermediate structures are predicted before proceeding with the tertiary structure prediction. Algorithms usually use the sequence of amino acids in the primary sequence to decide how to proceed in the prediction phase. Only C- α atoms in amino acids are considered, in order to simplify the model. At the end of the process, the backbone and the side chains are reconstructed by using statistical approaches to obtain a full-atoms protein structure prediction. A typical tertiary structure prediction workflow starts from the primary structure of the target and predicts a set of intermediate structures describing various chemical and structural features of the target. 1D structures characterize local features along the amino acid sequence of the target, for instance: (i) Secondary structure, which highlights high ordered subsequences along the α -carbon trace, (ii) contact and solvent accessibility, which predicts which contacts will be exposed to ligands and solvents and which will be buried inside the structure, (iii) disorder, useful to predict which contacts will be in a highly disordered state (Mirabello and Pollastri, 2013; Walsh *et al.*, 2011). 2D structures contain translation and rotation invariant topological information of the target protein, some of which are: (i) Coarse topology, is a matrix containing information about amino acids being in contact or not, (ii) contact map is also a matrix representing distances between α -carbon atoms of each amino acid along the chain, usually in 4 classes (0–8Å, 8–13Å, 13–19Å, >19Å) (Tradigo *et al.*, 2011; Tradigo, 2013) and, more recently by using continuous real values (Kukic *et al.*, 2014). All of these intermediate predicted structures are then used by the folding algorithms to reconstruct a fold of the α -carbon trace by using an heuristic (e.g., simulated annealing). The obtained minimum energy structure is finally enriched by reconstructing its backbone (Maupetit *et al.*, 2006) and its complete side chain (Krivov *et al.*, 2009; Liang *et al.*, 2011). In the following we will give some more details about this process.

The primary sequence, or sub-portions of it, are used as queries to search for homologues in databases containing known sequences (e.g., the PDB). This step has been shown to be crucial in order to exploit evolutionary information, since similar structures imply similar functions for protein molecules, due to evolutionary mechanisms, which promote changes at the morphological level, at the DNA level, at the cell pathways level and at the protein level. However, protein functions have to be maintained hence specific 3D structures are preserved, leading to protein portions known as domains. Two naturally evolved

proteins with more than 25% identical residues (length > 80 amino acids) are very likely to have similar 3D structures (Doolittle, 1986). Results obtained during this phase can be classified into three main classes (Schwede *et al.*, 2009): (i) Homology modeling, also called comparative modeling, where proteins similar to the target with known sequence have been found hence an atomic model for the target protein can be calculated from the known template structures (Petrey and Honig, 2005; Schwede *et al.*, 2003); results obtained are often good with prediction accuracy $\sim 80\%$; (ii) fold recognition, where no satisfying sequence alignment has been found but there exists known proteins with similar shape, hence information on the structure can be gathered from alignment against these known folds (Ye and Godzik, 2003); prediction accuracy lowers and is usually dependent on the implemented method; (iii) ab-initio or de-novo modeling, where none of the above applies, hence the atomic model of the target has to be derived directly from the primary sequence (Das and Baker, 2008); results in this class are usually quite poor, with a prediction accuracy below 30%.

Secondary structures are 1D predicted features allowing for a drastic cut in the phase space search for models with minimal energy. Alpha-helices and beta-sheets, whose shape is implied by hydrogen bonds among amino acids along the c-alpha trace, can in fact be considered as “fixed” geometrical elements, since they represent almost rigid structures in the real protein, due to the hydrogen bonds between the amino acids forming them. As shown In Rost, Sander, Schneider (1994), also secondary structure prediction gains from exploiting evolutionary information, bringing 68% predictive accuracy of using basic neural network approaches, to 70% accuracy, as shown in Holly and Karplus (1989).

Contact Maps are 2D predicted features which can guide the folding algorithm during the search towards the minimal energy structure. They encode a prediction for the topology of the target structure in a bi-dimensional matrix in whose elements the distance between each residue is stored. Typically, the distance is predicted in four classes, as seen above, where smaller distance classes are usually more easy to predict than larger ones. However, the prediction of contact maps represents an unbalanced problem as far fewer examples of contacts than non-contacts exist in a protein structure (Kukic *et al.*, 2014).

When all of the intermediate structures have been predicted, the folding algorithm starts from an almost linear backbone and iteratively moves each atom to a new close position which minimizes energy and does not violate the topological and energetical constraints encoded in the intermediate structures. This process is repeated until the structure total energy falls below a predefined threshold.

Analysis and Assessment

A typical concern about predicted protein structures is about their reliability and about the resolution that can be achieved with state of the art algorithms, which is of utter importance for biologists or physicians. Predicted structures can be used in many application scenarios, but much depends on how the obtained structure quality is measured, which in the past has been quite controversial (Schwede *et al.*, 2009). To this end, a dedicated research topic deals with structural quality to assess the quality of predicted structure and their potential use in various applications. When errors, usually measured in RMSD (Root-Mean-Square Deviation), in the structure are around 1Å, the obtained models can be used to study catalytic mechanisms and functions. When errors are below 3Å, the predicted structure can be used from molecular replacement studies (higher quality) to modeling to low resolution density maps (lower quality), depending on the quality. When errors are above 3Å, which is probably due to a sub-optimal template selection or an ab-initio modeling, the resulting model can be used just for domain boundaries or for the identification of structural motives.

One of the most important research initiative about finding a principled solution to the PFP is the CASP experiment (Moult *et al.*, 2014). This large international experiment involves a large scientific research community working on state of the art protein structure prediction models and well principled algorithmic approaches. At present time, CASP has been held in 12 editions, both in Europe and in the United States, with a bi-annual schedule starting from 1994. CASP is held every two years in the form of a competition, in which participants enroll to a blind challenge for the prediction of a set of few hundreds “unknown” protein targets, which will be solved with exact methods (e.g., X-ray crystallography) by the end of the experiment. Predictions can be computer- and human-based, and also combined (i.e., human-curated predictions). Also, in the competition there exist raw methods, which build the structure prediction from scratch, and also metapredictors, which integrate prediction from other tools. At the end of the experiment, all targets get resolved and a dedicated team proceeds with the assessment by comparing predicted structures with the observed ones.

Like predictors, metapredictors take a primary structure as the input and return a prediction of its secondary or tertiary structure as the output (Palopoli *et al.*, 2013). Metapredictors compute their results based on prediction results taken from other prediction tools. Intermediate predictions are then elaborated by using two main approaches, leading to two kinds of metapredictors: (i) Consensus-based methods (see Mihășan, 2010; Bujnicki and Fischer, 2008), query different prediction servers and choose the best structure according to specific metrics, but they are only able to ideally perform as good as the best predictor they use; (ii) integration methods (see Bujnicki and Fischer, 2008; Palopoli and Terracina, 2004; Palopoli *et al.*, 2009) retrieve predicted structures from several prediction servers, extract relevant structural features and produce a supposedly superior model based on them, usually showing better performances than consensus-based methods, because they are able to combine local features, but when dealing with predictions being significantly different from one another. Furthermore, they go beyond the selection of the “best models”, because they generate a completely new structure.

In order to assess predictions for the target protein, different measures are usually used to compare the predicted structure with the observed one. Q3 and SOV (Rost *et al.*, 1994; Zemla *et al.*, 1999) are numerical measures which can assess the prediction

performance of a secondary structure predictor. Q3 measures the percentage of residues assigned to the correct class (i.e., alpha-helix, beta-sheet, loop) and is the average of several measures Q_i ($i = \{\text{helix, sheet, loop}\}$), where Q_i is the percentage of residues correctly predicted in state i with respect to the total number of residues experimentally observed in state i . SOV, which stands for Segment Overlap, gives a measure of correct assignments by-segment which is less sensitive to small variations. For the assessment of contact maps predictions, X_d and Z_{acc} measures are used (Moult, 2013). X_d takes into account the correctly assigned contacts in bands from the main diagonal (0–4Å, 4–8Å, 8–12Å, etc). Z_{acc} (z-accuracy) is the percentage of correctly predicted contacts with respect to total contacts. Contact maps prediction tools are then ranked according to the Z_{total} score, which averages the X_d and Z_{acc} measures calculated on each target predicted by the tool. One of the most diffuse tools for assessing 3D structures is the TMScore tool (Zhang and Skolnick, 2007). TMScore gives a length-independent score in the range (0,1] which allows predictions to be compared to each other and is less sensitive to local variations in the structure, being a global fold similarity. Other methods for the comparison of 3D structures do exist in literature (see Cristobal *et al.*, 2001; Siew *et al.*, 2000).

Biographical Sketch

Giuseppe Tradigo is a postdoc at the DIMES Department of Computer Science, Models, Electronics and Systems Engineering, University of Calabria, Italy. He has been a Research Fellow at University of Florida, Epidemiology Department, US, where he worked on a GWAS (Genome-Wide Association Study) project on the integration of complete genomic information with phenotypical data from a large patients dataset. He has also been a visiting research student at the AmMBio Laboratory, University College Dublin, where he participated to the international CASP competition with a set of servers for protein structure prediction. He obtained his PhD in Biomedical and Computer Science Engineering at University of Catanzaro, Italy. His main research interests are big data and cloud models for health and clinical applications, genomic and proteomic structure prediction, data extraction and classification from biomedical data.

Francesca Rondinelli is a young researcher. She obtained her PhD in Theoretical Chemistry at University of Calabria, Dept. of Chemistry. She has been visiting research student at KTH Royal Institute of Technology in Stockholm, Department of Chemistry. She has been a postdoc both at University of Calabria and at University of Naples, Federico II. Her research interest go from cyclodextrins, principled drug design and CO₂ activation.

Gianluca Pollastri is an Associate Professor in the School of Computer Science and a principal investigator at the Institute for Discovery and at the Institute for Bioinformatics at University College Dublin. He was awarded his M.Sc. in Telecommunication Engineering by the University of Florence, Italy, in 1999 and his PhD in Computer Science by University of California at Irvine in 2003. He works on machine learning and deep learning models for structured data, which he has applied to a cohort of problems in the bioinformatics and chemoinformatics space. He has developed some of the most accurate servers for the prediction of functional and structural features of proteins, which have processed over a million queries from all over the world and have been licensed to 75 different subjects, including pharmaceutical companies. His laboratory at UCD has been funded by Science Foundation Ireland, the Health Research Board, the Irish Research Council, Microsoft, UCD, the King Abdulaziz City for Science and Technology (Saudi Arabia) and Nvidia.

Algorithms for Structure Comparison and Analysis: Homology Modelling of Proteins

Marco Wiltgen, Graz General Hospital and University Clinics, Graz, Austria

© 2019 Elsevier Inc. All rights reserved.

Introduction

Protein structure is uniquely determined by its amino acid sequence. Knowledge of protein 3D structure is of crucial importance for understanding protein function, dynamics and interactions with ligands and other proteins (Lesk, 2001, 2002; Gibas and Jambeck, 2001; Chang, 2005). A protein cannot be seen, for example, by a microscope with X-ray focussing lenses. Therefore there exists no real image, such as a microscopic view of a cell, of a protein. Instead we must use structural models of the proteins, based on X-ray diffraction data, NMR data etc. (Wiltgen, 2009). Current experimental structure determination methods such as X-ray crystallography and nuclear magnetic resonance (NMR) are slow, expensive, and often difficult to perform (Kendrew *et al.*, 1960). X-ray crystallography delivers high resolution protein structures whereas NMR is restricted to limited size proteins in solution resulting in low-resolution structures. Many proteins are too large for NMR structure determination and others cannot be crystallized for X-ray diffraction. In addition in the experimental determination of a protein structure there occasionally arise problems concerning the cloning, expression, purification and crystallization of the protein. If the experimental techniques fail then protein modelling on a computer is the only way to obtain structural information (Chou, 2006). Although experimental methods are nowadays in some sense high throughput processes, they cannot keep up with the growth rate of known protein sequences. For example the protein structural database (PDB) today contains (06/2017) 131,485 macromolecular structures (Berman *et al.*, 2000). Of these, 36,528 entries are from *Homo sapiens*, 8563 from *Escherichia coli*, 5582 from *Mus musculus*, 3712 from *Saccharomyces cerevisiae* and so on (it should be noted that these numbers includes multiple solutions of the same structure). In contrast the UniProtKB/TrEMBL database contains 87,291,332 sequence entries. Therefore computational methods for the prediction of protein structure have gained much interest.

Among computational protein modelling methods, homology modelling, also known as template-based modelling (TBM) usually provides the most reliable results (Xu *et al.*, 2000; Kryshchak *et al.*, 2017). The method is based on the observation that two proteins belonging to the same family, and therefore sharing very similar amino acid sequences, have similar three-dimensional structures (Sanchez and Sali, 1997a, b). In homology modelling, a protein sequence with an unknown structure is aligned with sequences that have known protein structures (Schwede *et al.*, 2000). By exploiting structural information from the known configurations, the new structure can be predicted. Homology modelling is based on two important observations in nature: The structure of a protein is determined by its amino acid sequence, and the structure itself is more conserved than the sequence during evolution. Local changes in the amino acid sequence often cause only small structural changes. Therefore homology modelling first involves the finding of already known homologous protein structures and then building the query (target) sequence into the homologous template structures. Because most protein families contain at least one member with a known structure, the applicability of homology modelling is steadily increasing.

Homology-based models can be used to guide the design of new experiments, such as site-directed mutagenesis, and are valuable in structure-based drug discovery and design. In structural bioinformatics many public software tools and data bases are used for the analysis of macromolecules. Several of them are presented in this article.

Bioinformatics Tools for Protein Structure Prediction and Analysis

A number of bioinformatics tools for proteomic analysis are available at the ExPASy server at website provided in “Relevant Websites section” The software tools include functions such as protein identification and characterization such as: predicted isoelectric point, molecular weight, amino acid composition and predicted mass spectra, and others (Gasteiger *et al.*, 2003). Additionally similarity searches using pattern and profile searches can be used to identify homologous or structurally similar protein structures.

Two popular programs for homology modelling, that are free for academic research, are MODELLER (see “Relevant Websites section”) and SWISS-MODEL (See “Relevant Websites section”). The Modeller program can be used as standalone software whereas SWISS-MODEL is a Web-based fully automated homology modelling server (Eswar *et al.*, 2008; Webb and Sali, 2014). Homology modelling is initiated by inserting the target sequence into the entry field of the SWISS-MODEL server (Schwede *et al.*, 2003). After selecting the templates from a list proposed by the system, all the subsequent steps in homology modelling are carried out automatically. SWISS-MODEL is accessible via the ExPASy web server, or from the viewer program DeepView (Swiss PDB viewer). The purpose of this server is to make protein modelling accessible to all biochemists and molecular biologists worldwide. The Swiss PDB viewer can be freely downloaded from the Swiss PDB viewer server (see “Relevant Websites section”) and used for molecular analysis and visualization (Guex and Peitsch, 1997). As input, the program uses coordinate files from protein structures at the PDB database for the template structures. The atomic coordinates are then converted into a view of the protein. Some additional software tools for protein structure prediction based on homology modelling and threading are listed in Table 1 (this list is far from complete).

Table 1 Listed are some representative examples of Template Based Modelling (TBM) and Free Modelling (FM) software tools (also known as *ab initio* modelling)

QUARK	FM	Webserver	http://zhanglab.ccmb.med.umich.edu/QUARK/

The entry point to the structural protein database is the PDB web site: website provided in “Relevant Websites section”. The search for a particular protein structure of interest can be initiated by entering the 4 letter PDB identification code at the PDB main page (Sussman *et al.*, 1998). Alternatively, the PDB can be searched by use of keywords. Convenient access to the PDB and many other databases is enabled by the *Entrez* integrated search and retrieval system of the NCBI (National Centre for Biotechnology Information, see “Relevant Websites section”). Structures in the structural database can be identified by searching using specific keywords such as the name of the protein or organism, or other identifying features such as the names of domains, folds, substrates, etc. (Baxeianis, 2006). Keywords can be used to search for information in the most important fields in the PDB data header. The advantage of access via NCBI is the availability of public domain tools like BLAST (Basic Local Alignment Search Tool) which enables the user to compare an uncharacterized protein sequence with the whole sequence database (Altschul *et al.*, 1990, 1997).

Protein Families and the SCOP Database

Proteins always exist in aqueous solutions. To minimize the energy cost of solvating a protein, it is favourable that hydrophilic amino acids are arranged to be solvent exposed at the protein surface, whereas the hydrophobic amino acids are mainly concentrated in the protein core. This may limit the number of occurring structure motifs (folds) which are repetitively used in different proteins. Therefore the evolution of proteins is restricted to a finite set of folds resulting in proteins with structural (native conformation) and sequence similarities (Hubbard *et al.*, 1997).

The Structural Classification of Proteins (SCOP) database provides a detailed and comprehensive description of the structural and evolutionary relationships between all proteins whose structure is known. The SCOP is a database maintained by the MRC Laboratory of Molecular Biology, UK (see “Relevant Websites section”). (The prototype of a new Structural Classification of Proteins 2 (SCOP2) is available at see “Relevant Websites section”). Proteins are classified in a hierarchical way (Murzin *et al.*, 1995). At the top of the hierarchy are classes, followed by folds, superfamilies and families (Fig. 1). At the class level, folds are characterized by their secondary structure and divided into all-alpha (α), all-beta (β) or mixed alpha-beta (α/β , $\alpha + \beta$) structures.

Families: Proteins with a close common evolutionary origin are clustered together in families. The members of a family have significant sequence similarity leading to related structures and functions. The protein molecules have a clear homology.

Superfamilies: If the proteins of different families have only low sequence similarity, but their structures are similar (which indicates a possible common evolutionary origin), then these families are clustered together as a superfamily.

Folds: If the proteins included in superfamilies have the same major secondary structures arranged in the same way and with the same topological connections then they belong to the same fold (similar topology).

Class level: The different folds (with different characteristics) are clustered into classes. Thereby the folds are assigned to one of the following structural classes: folds whose structure contains essentially only α -helices, folds whose structure is essentially composed of only β -sheets, and folds composed of both α -helices and β -sheets.

In addition to the SCOP database, the CATH database provides a similar hierarchical classification of protein domains based on their folding patterns (Knudsen and Wiuf, 2010). The 4 main levels of the CATH hierarchy are: Class (equivalent to the class level in SCOP), Architecture (equivalent to the fold level in SCOP), Topology, and Homologous superfamily (equivalent to the superfamily level in SCOP).

Proteins that have grossly similar structures are classified as more closely related (Andreeva *et al.*, 2008). This plays an important role in the search and detection of homology. In the SCOP database, the amino acid sequence identity within a protein family must be at least > 15%. The prerequisite for successful homology modelling is sequence identity of at least 25%–30% between the target sequence and the template sequences. Therefore homology modelling works very well for proteins inside a family.

Substitution Matrix and Sequence Alignment

Sequence alignment is a way of arranging protein (or DNA) sequences to identify regions of similarity that may be a consequence of evolutionary relationships between the sequences. The rate at which an amino acid in a protein sequence changes to another

Fig. 1 The Structural Classification of Proteins (SCOP).

over time is described by substitution matrices. The elements of a (20×20) substitution matrix define the score for the alignment of any two of the 20 amino acids (Henikoff and Henikoff, 1992). Because the score for aligning residues A and B is normally the same as for B and A, the substitution matrix is symmetric.

The alignment score describes the overall quality of a sequence alignment. Higher numbers correspond to higher similarity. The calculation of the score is as follows. Given a sequence pair (S_1, S_2) of length N respectively M:

$$S_1 = a_1 a_2 \dots a_i \dots a_N \quad ; \quad S_2 = b_1 b_2 \dots b_j \dots b_M$$

The symbols in the sequences are elements of the set of amino acids:

$$a, b \in \{ \underbrace{\{A, R, N, D, C, Q, E, G, H, I, L, K, M, F, P, S, T, W, Y, V\}}_{20 \text{ amino acids (1 letter symbol)}} \}$$

The indexes i and j refer to the position of an amino acid a_i and b_j in the respective sequences. To determine a score for the alignment we first consider the case that the two sequences are not related, and then the case that the sequences are related, which means they are descended from a common ancestor. Assuming the amino acid residues are randomly distributed, the probability

of an alignment of two sequences that are not related is given by the product of the probabilities of the independent amino acids:

$$P(R; S_1, S_2) = \prod_i q_{a_i} \cdot \prod_j q_{b_j}$$

The probability q_{a_i} is called the background frequency and reflects the natural occurrence of the amino acid a at position i . The alignment is given by chance (R : randomly). If the two sequences are related (belonging to the same family) the residue pairs in the alignment occur with a joint probability, p_{ab} . This probability reflects the natural exchange rate, over evolutionary time, of the considered amino acids in related proteins. In other words, p_{ab} describes the probability that the residues a and b are descended from a common ancestor.

The probability for a successful matching (M) of the two sequences is given by:

$$P(M; S_1, S_2) = \prod_i p_{a_i b_i}$$

The ratio of the probabilities for the exchange of residues a and b in the related and unrelated models is given by the odds-ratio:

$$\frac{P(M; S_1, S_2)}{P(R; S_1, S_2)} = \frac{\prod_i p_{a_i b_i}}{\prod_i q_{a_i} \cdot \prod_j q_{b_j}} = \prod_i \frac{p_{a_i b_i}}{q_{a_i} q_{b_j}}$$

To obtain an additive scoring system we take the logarithm of the odds ratio:

$$S = \log \prod_i \frac{p_{a_i b_i}}{q_{a_i} q_{b_j}} = \sum_i s(a_i, b_i)$$

The value S is called the log-odds ratio and $s(a_i, b_i)$ is the log-odds ratio for the residue pair a, b and is given by [Dayhoff et al. \(1978\)](#):

$$s(a, b) = \log \left(\frac{p_{ab}}{q_a q_b} \right)$$

If the joint probability is greater than the product of the background frequencies ($p_{ab} > q_a q_b$) then the value of the log-odds ratio is positive. If $q_a q_b > p_{ab}$ then the value is negative. The raw scores for every possible pairwise combination of the 20 amino acids are entered in the substitution matrix (also called scoring matrix). As an example the BLOSUM 62 (BLOCKS SUBstitution Matrix) matrix is shown in [Fig. 2](#). The log-odds ratio evaluates the probability that the residue pair a, b originates from an amino acid exchange in the equivalent position of an ancestral protein relative to the probability that the correlation is only by chance. The score of the alignment is then the sum of the individual log-odds ratios for every residue-pair in the alignment. If a gap occurs in the alignment, a penalty is subtracted from the total score. The above considerations about the probabilities of amino acid exchanges are the empirical basis for the understanding of substitution matrices, the values themselves are determined from

experimental data. A high alignment score indicates that the two sequences are very similar. The values along the diagonal in the substitution matrix are highest because, at relatively short evolutionary distances, identical amino acid residues are more likely to be derived from a common ancestor than to be matched by chance. Two residues have a positive score if they are frequently substituted for one other in homologous proteins. The alignment between residues that are rarely substituted in evolution, results in a lower (or negative) score.

The Protein Data Bank

Protein structural information is publicly available at the protein data bank (PDB), an international repository for 3D structure information (Sussman *et al.*, 1990; Rose *et al.*, 2017). At the moment, PDB contains more than 123,000 protein structures. The structural information is stored as atomic coordinates (Fig. 3). The B-factor, also called the temperature factor, defines the modelled isotropic thermal motion. Beside the B-factor, the occupancy value is stored in the PDB file. For structure determination with X-ray diffraction, macromolecular crystals are used. These crystals are composed of individual molecules which are symmetrically arranged. Because side chains on the protein surface may be differently orientated, or substrates may bind in different orientations in an active site, slight differences between the molecules in the crystal are possible. The occupancy is used to estimate the amount of conformations in the crystal. For most atoms, the occupancy value is 1.00, indicating that the atom is in all of the molecules in the same place in the crystal.

The database can be accessed via the Internet and the selected PDB data files, containing the atomic coordinates, are downloadable (Westbrook and Fitzgerald, 2003). Appropriate viewer programs, such as the Swiss PDB viewer, convert the atomic coordinates into a view of the protein. The coordinates of the templates are used for the homology modelling.

Homology Modelling

During protein evolution, protein structures show higher conservation than the corresponding sequences, so that distantly related sequences still fold into similar structures (Johnson *et al.*, 1994; Kaczanowski and Zielenkiewicz, 2010). Homology modelling is based on the principle that homologous proteins tend to have similar structures. Homology-based modelling is a knowledge-based prediction of protein structures that uses parameters extracted from existing structures to predict a new structure from its sequence (Sanchez and Sali, 2000). When no homologous sequences with known structure can be identified, then *ab initio* structure prediction, based on the first principle laws of physics and chemistry is used (Table 1). Thereby only relatively small protein structures can be predicted.

Therefore the determination of the tertiary structure of a given protein sequence (target) is based on an alignment of the target sequence with one or more sequences with known protein structures (templates). Hence homology modelling first involves the finding of known protein template structures, and then the target sequence is built into the homologous template structures. The steps required in homology modelling are as follows:

- 1) Identification of template structures: The target sequence (with unknown structure) is used as a query to find homologous sequences with known structures (the templates).
- 2) Sequence alignment: The amino acid sequences of the target and the templates are brought into an optimal (multiple) alignment.
- 3) Backbone generation: Information from the template backbones is used to model the structural backbone of the target sequence.
- 4) Generation of loops: Loop-modelling procedures are used to fill gaps in the alignment.

Fig. 4 Pipeline of a composite protein structure prediction: If homologous structures are available the prediction starts with an alignment of the target sequence and template sequences. If no homologous structures are available, then *ab initio* modelling is applied.

- 5) Insertion of side chains: The amino acid side chains are added to the backbone and their positions are optimized.
- 6) Model optimization: The generated structure is optimized by energy minimization

Homology modelling is based on a biological perspective: Homologous proteins have evolved by molecular evolution from a common ancestor. By identifying homology, the structure and function of a new protein can be predicted based on the homolog (Fig. 4). There is also a physical perspective: The structure of a protein corresponds to a global free energy minimum of the protein and solvent system. A compatible fold can be determined by threading the protein sequence through a library of folds, and empirical energy calculations used to evaluate compatibility (Ambrish and Yang, 2012).

If a homology between the target sequence and the template sequence is detected, then structural similarity can be assumed. In general, at least 30% sequence identity is required to generate a useful model. If the sequence identity in the alignment is below 30%, depending on the number of aligned amino acid pairs, then they fall in the twilight zone and random alignments begin to appear (Fig. 5).

Principles of Homology Modelling

In order to illustrate the principles of homology modelling, I present an example of predicting the structure of orotidine 5'-monophosphate decarboxylase from its sequence (Harris *et al.*, 2002). Orotidine 5'-monophosphate (OMP) decarboxylase is an enzyme which is essential for the biosynthesis of the pyrimidine nucleotides (cytosine, thymine, and cytosine uracil). It catalyzes the decarboxylation of orotidine monophosphate to form uridine monophosphate. OMP-decarboxylase belongs to the decarboxylase protein family, which is highlighted in Fig. 1.

Search for homologous template sequences

An optimal alignment can be calculated by the dynamic programming algorithm (Needleman and Wunsch, 1970). Such global alignments are mainly used for sequences of similar lengths and where a strong sequence homology is expected. (In contrast to most modern dynamic programming tools, the Needleman-Wunsch method uses a length independent penalty). To identify sequence

Fig. 5 The two zones of sequence alignments. Two sequences fold with high probability into a similar structure if their length and percentage sequence identity fall into the homology modelling zone.

motifs in protein sequences, local alignments are used (Smith and Waterman, 1981). Thereby the similarities of local regions in the sequences, which may differ in the rest of the sequence, are evaluated. In practice the methods of dynamic programming are too slow for searching the fast growing sequence databases. Therefore heuristic approaches are used instead of optimal solutions.

BLAST (Basic Local Alignment Search Tool) is a heuristic algorithm for comparing protein or DNA sequences (Altschul *et al.*, 1990). BLAST approximates the Smith-Waterman algorithm. A BLAST search compares a query sequence to sequences within sequence databases and retrieves sequences that resemble the query sequence, above a certain threshold. The basic idea of BLAST is that a significant alignment of two sequences contains short sections with a high score, called high-scoring segment pairs (HSP). First, from the protein query sequence a list of short words (containing 3 residues) is generated:

```
Sequence :  --LDYHNR--
word1 :    LDY
word2 :    DYH
word3 :    YHN
word4 :    HNR
```

These words are used for the database search. Actually, a key concept of BLAST is that it is not just identical matching; a neighborhood of matching words is generated for each word in the query sequence. If a word in the list is found in the database, then starting from the word the alignment between the query and target sequence is enlarged in both directions until a maximal score is reached (Fig. 6). The detected HSP's are then entered into the list of results. For a HSP to be selected its score must exceed a cut-off score S that is given by the predefined expectation-value (see below). To evaluate the significance of a BLAST search, the following question is of special importance: Given a particular scoring system, how many unrelated sequences would achieve an equal or higher score?

Almost all the relevant statistics for local alignment scores can be understood in terms of the expectation-value. The expectation-value (E-value) is the number of distinct alignments, with a score greater than or equal to S that are expected to occur in a database search by chance. The lower the E value, the more significant the alignment is. The E-value of an (un-gapped) alignment, between sequences of length m , respectively length n , is related to the score S by the Karlin-Altschul equation:

$$E = Kmn e^{-\lambda S}$$

Where S is the raw score of an alignment, obtained by summing the scores of each pair of amino acids in the alignment (see "Substitution matrix and sequence alignment"), and K and λ are constants that depend on the scoring matrix (Karlin and Altschul, 1990). The probability of finding at least one alignment with a score $\geq S$ is given by:

$$p = 1 - e^{-E}$$

This is called the p-value associated with S . The normalized bit-score S' is a rescaled version of the raw alignment score, expressed in bits of information. The parameters K and λ are folded into the bit-score by the following linear transformation:

$$S' = \frac{\lambda S - \ln K}{\ln 2}$$

(In current implementations of BLAST, the alignment score reported is the normalized bit score). By use of the bit-score the equation for the E-value reduces to:

$$E = mn 2^{-S'}$$

The orotidine 5'-monophosphate decarboxylase sequence is used as a query to search the PDB database for homologous sequences with known structures. To this end, the program BLAST was used, wherein the query sequence is entered via a simple web form (see "Relevant Websites section"). The search is restricted to the PDB database and therefore only sequences with known

Fig. 6 BLAST search procedure.

Table 2 Template sequences

<i>OMP-decarboxylase</i>	<i>PDB code</i>	<i>Expectation value E</i>	<i>Residue identity</i>	<i>Similarity</i>	<i>Length</i>	<i>Gaps</i>
<i>Vibrio Cholera</i>	3LDV_A	5e-117	70%	80%	231	0%
<i>Coxiella Burnetii</i>	3TR2_A	7e-73	49%	64%	219	0%
<i>Lactobacillus Acidophilus</i>	3TFX_A	6e-50	39%	56%	231	2%

structures are taken into consideration. Blast compares the query sequence to all the sequences of known structures in the PDB database. The BLAST program lists several alignments of the query sequence with subject sequences with E-values below the selected threshold; The alignments are sorted by the E-values. Alignments with low E-values are very significant, which means that the sequences are likely to be homologous.

As a result, the sequences of orotidine 5'-monophosphate decarboxylase from *Vibrio cholerae*, *Lactobacillus acidophilus*, and *Coxiella Burnetii* were selected as likely to be homologs (Franklin *et al.*, 2015). The amino acid identity for all the template sequences is above 30% (Table 2). Similarity indicates the percentage of aligned amino acids that are not identical, but have positive values in the substitution matrix, and therefore frequently substituted. An optimal alignment shows a considerable number of identical or similar residues and only infrequent and small gaps.

Multiple alignments

A multiple sequence alignment is the alignment of three or more amino acid (or nucleic acid) sequences (Wallace *et al.*, 2005; Notredame, 2007). Multiple sequence alignments provide more information than pairwise alignments since they show conserved regions within a protein family which are of structural and functional importance.

Fig. 7 shows the target sequence arranged in a multiple alignment with the template OMP-decarboxylases from *V. cholerae*, *L. acidophilus*, and *C. burnetii*. The alignment was made with the MULTALIN multiple alignment tool (Corpet, 1988). The sequence alignment is used to determine the equivalent residues in the target and the template proteins.

The corresponding superposition of the template structures is shown in Fig. 8. After a successful alignment has been found, the actual model building can start.

Backbone generation

Proteins are polymers of amino acids, which consist of an amino group, a carboxyl group, and a variable side chain. The amino acids are connected by a peptide bond between the amino group and the carboxyl group of adjacent amino acid residues in the polypeptide chain. The amide nitrogen, α -carbon, and carbonyl carbon, are referred to as the backbone.

Creating the backbone scaffold can be trivially done by simply copying the coordinates of the template residues. More sophisticated procedures exploit structural information from combinations of the template backbones. For example, the target backbone can be modelled by averaging the backbone atom positions of the template structures, weighted by the sequence similarity to the target sequence (SWISSMODEL, Peitsch, 1997). Fig. 9 shows the target backbone superimposed on a ribbon diagram of one of the template structures.

Other homology modelling procedures rely on rules based on spatial restraints such as spacing between atoms, bond lengths, bond angles, and dihedral angles (Sali and Blundell, 1993). These rules are derived from observed values in known protein structures.

Fig. 7 Multiple alignment of the target sequence with the template sequences.

Fig. 8 Cartoon diagram of the superposition of the three template structures in Fig. 7.

Generation of loop structures

In most cases, the alignment between the query and template sequence contains gaps. Thereby the gaps can be either in the target sequences (deletions) or in the template sequence (insertions). Deletions create a hole in the target that must be closed. In the case of insertions, the backbone of the template is cut and the missing residues inserted. Both cases imply a conformational change of the backbone. For insertions in the target, no structural information can be derived from the template structures. In contrast the template structures provide a great deal of information for deletions in the target.

Fig. 9 In the figure, the target backbone (ball-and-stick representation) is superimposed on a cartoon representation of the 3ldv template structure (represented by a ribbon). Alpha helical regions of the template structure are shown in red, and beta strand regions are shown in yellow.

Fig. 10 illustrates the addition of a loop segment of appropriate length to the structural model (see below). It should be noted that this is only an illustrative example, and the alignment (with gap) was made with a template structure not contained in [Table 2](#).

The gaps in an alignment can be filled by searching for compatible loop fragments derived from experimental structures. Two main approaches to loop modelling can be distinguished:

1. Knowledge based approach: The PDB is searched for known loops with endpoints matching the residues between which the loop has to be inserted. Several Template Based Modelling programs such as: Swiss-Model and Modeller support this approach. If a suitable loop conformation is found, it can be simply copied and connected to the endpoint residues to fill the gap.
2. Energy based: Candidate loops are generated by constructing fragments, compatible with the neighbouring structural elements. An energy function (or force field) (Section “Molecular Force Fields”) is used to evaluate the quality of the loop. To get the optimal loop conformation the energy function is minimized, for example by Monte Carlo simulation ([Simons et al., 1999](#)) or molecular dynamics techniques, and evaluated by a scoring system ([Fiser et al., 2000](#)). The scoring system accounts for conformational energy, steric hindrance, and favourable interactions such as hydrogen bonds.

There are several reasons for different loop conformations in the template and model structures: Surface loops tend to be involved in inter-molecular interactions, resulting in significant conformational differences between the query and template structures. The exchange of small sidechains with bulky side chains pushes the loop aside. The exchange of a loop residue with a proline, or from glycine to any other residue, requires conformational changes in the loop. For short loops the methods listed above can predict a loop conformation that fits well in true structures ([Tappura, 2001](#)).

Fig. 10 Loop-modelling procedures are used to fill gaps (red) in the alignment.

Insertion of side chains

20 different amino acids are commonly found in protein sequences. Each of the 20 amino acids has a different side chain (R-group), which is responsible for its unique physicochemical properties. For instance, some of the side chains have ring like structures (aromatic), while others consist of unbranched carbon chains (aliphatic).

Side chain conformations are derived from those observed in similar structures and from steric considerations. Starting from the most conserved residues, the side chains are inserted by isosteric replacements (side chains with similar shapes and physicochemical properties) of the template side chains (Fig. 11). Amino acids that are highly conserved in structurally similar proteins often have similar side chain torsion angles. This is especially true when the amino acid residues form networks of contacts. Therefore such conserved residues can be copied in their entirety from the template structure to the model. Thereby a higher accuracy can be achieved than by copying just the backbone and predicting the side chain conformations (Sanchez and Sali, 1997a, b).

The most successful approaches to side-chain placement are knowledge based, relying on rotamer libraries tabulated based on high-resolution X-ray structures (Dunbrack and Karplus, 1994). Such libraries are built by taking high-resolution protein structures and collecting all stretches of a set of residues with a given amino acid at the centre. A preferred rotamer is identified by superimposing the corresponding backbone of an amino acid in the template on all the collected examples. Then the possible side-chain conformations are selected from the best backbone matches. A scoring function that evaluates favourable interactions, such as hydrogen bonds and disulphide bridges, and unfavourable interactions, such as steric hindrance, is used to select the most likely conformation. Various possible rotamers are successively tested and scored with energy functions (or force field, see Section

Fig. 11 The model structure after the side chains have been added to the target backbone by isosteric replacement of the side chains in the template structures. The replacement procedure relies on rules for dihedral and bond angles, and uses observed values in known protein structures to help optimize the positions of the side chains.

“Molecular Force Fields”). Because the choice of a rotamer automatically affects the rotamers of all the amino acid residues that make side chain contacts, this leads to a combinatorial explosion of the search space. Therefore, various methods have been developed to make this enormous search space tractable. For example a hydrogen bond between the side chain and backbone favors certain rotamers and thus greatly reduces the search space.

The rotamer prediction accuracy is usually high for residues in the hydrophobic protein structure core, but much lower for residues on the surface. The reasons are as follows: The flexible side chains on the surface tend to adopt multiple conformations. The energy functions used to score rotamers are well suited for evaluating the hydrophobic packing of the core, which results mainly from van der Waals interactions. But the electrostatic interactions on the surface, including hydrogen bonds with water molecules and associated entropic effects, are not handled with similar precision.

Some useful software tools for sequence alignment, loop prediction, and side chain modelling are listed in [Table 3](#).

Molecular Force Fields

In the rigid modelling procedure, described above, distortions such as: clashes between atoms; longer than normal bond lengths; unfavourable bond angles, etc., may occur, resulting in energetically unreasonable conformations. For example, steric hindrance results from overlapping of the van der Waals spheres associated with the residues, leading to strong repulsive forces. Such unrealistic distortions are removed by energy minimization techniques.

The determination of a geometrically optimal structure of a molecule, which means the structure with minimum free energy, is a further important step in homology modelling. The equilibrium free energy of a molecular structure is calculated by the use of molecular force fields. In computational physics and molecular modelling, a molecular force field is a mathematical function that describes the dependence of the potential energy of a molecule on the coordinates of its atoms. It is specified by an analytical form of the intermolecular potential energy: $U(r_1, r_2, \dots, r_N)$ and a set of input parameters. Force fields differ in their functional form as well as their fixed parameter sets ([Wang et al., 2000](#)). The parameter values are obtained either from quantum mechanical calculations (*ab initio* or semi-empirical methods), or by fitting to experimentally determined high resolution structures, determined by X-ray diffraction, nuclear magnetic resonance (NMR), infrared and Raman spectroscopy, and other methods. For the energy minimization of macromolecules, adequate molecular force fields such as AMBER, CHARMM, and GROMOS have been developed ([Christen et al., 2005](#)). In these approaches, the coordinates of all atoms of the macromolecule are treated as free variables ([Price and Brooks, 2002](#)). The basic functional form of a molecular force field includes terms for covalent bonds and terms for long-range forces (non-bonded interactions) inside the molecule:

$$U(r_1, r_2, \dots, r_N) = \underbrace{\sum_{\text{bonds}} K_r(r - r_0)^2 + \sum_{\text{bonds}} K_\theta(\theta - \theta_0)^2 + \sum_{\text{dihedrals}} V_n(1 + \cos(n\Phi))}_{\text{covalent bonds}} + \underbrace{\sum_i \sum_j \frac{q_i q_j}{r_{ij}} + \sum_i \sum_j \left(\frac{A_{ij}}{r_{ij}^{12}} - \frac{B_{ij}}{r_{ij}^6} \right)}_{\text{non-bonded interactions}}$$

The single terms and the symbols are explained in the following sections. Using such a force field model, macromolecules are reduced to a set of atoms held together by simple harmonic forces, Coulombic interactions, and van der Waals interactions. For practical calculations, the force field must be simple enough to be evaluated quickly, but sufficiently detailed to reproduce realistic structural properties.

Some popular molecular force fields are listed in [Table 4](#).

Covalent bond terms

For the covalent bond terms, parametrized by bond length, bond angles and dihedral angles, the potential energy is described relative to the atoms being in their equilibrium positions, for which the energy is taken to be zero.

- 1) The first term in the molecular force field describes the extension (stretching) of covalent bonds. Bond stretching is often represented by a simple harmonic function $K_r(r - r_0)^2$ that controls the length of covalent bonds ([Fig. 12](#)). This corresponds to a classical harmonic oscillator with spring constant: K_r . Realistic values for the equilibrium bond length r_0 are, for example, obtained experimentally by X-ray diffraction of small molecules. The spring constant (K_r) can be estimated from infrared or Raman spectra.

Bond lengths are determined by the electronic orbitals (s, p) of the involved atoms and the number of the shared electrons between the atoms. The harmonic potential is a poor approximation when the bond stretching exceeds displacements of more than 10% from the equilibrium value. Nevertheless, under most circumstances the harmonic approximation is reasonably good.

- 2) The second force field term describes the distortion of the bond angles ([Fig. 13](#)). Distortion of bond angles is described by the energy related to bending an angle, θ , formed by at least three atoms: A-B-C, where there is a chemical bond between A and B, and between B and C ([Fig. 14](#)). As in the case of bond stretching, the angle bending term is expanded as a Taylor series around the equilibrium bond angle, θ_0 , and terminated at the second order (harmonic approximation). The vibrational frequencies are in the near infrared spectrum, and the constant K_θ is measured by Raman spectra.
- 3) The third force field term describes the distortion of dihedral angles ([Fig. 15](#)) from their preferred values. If a molecule contains more than four atoms in a row, which is a given in macromolecules, the dihedral term must be included in the force

Fig. 15 Dihedral angle in 1,2-dichloroethane. This conformation corresponds to $\Phi = 180^\circ$. The energy of different conformations is shown in Fig. 16.

Fig. 16 Torsional potential of 1,2-dichloroethane as a function of the dihedral angle Φ . The potential energy minima are found at the gauche- ($\Phi = 60^\circ, 300^\circ$) and trans- ($\Phi = 180^\circ$) staggered conformations. The saddle points ($\Phi = 120^\circ, 240^\circ$) correspond to eclipsed (covered) conformations.

field. Dihedral angles are angles of rotation of the bonded atom pairs around the central bond. In stereochemistry, the dihedral is defined as the angle between planes through two sets of three atoms, which have two atoms in common (Fig. 16). Changes in dihedral angles often result in major conformational changes.

Fig. 16 shows the dihedral potential as a function of different conformations of 1,2-dichloromethane. The torsional motions in macromolecules determine the rigidity of the molecule. Therefore, they play an important role in determining local structures, such as reactivity centres, of a macromolecule. Additionally they play an important role in the relative stability of different molecular conformations. Bond stretching and angle bending motions are typically hundreds of times stiffer than torsional motions. Dihedral angles are mainly constrained by steric hindrance. Torsional energy is usually represented by a cosine function: $V_n(1 + \cos(n\Phi))$, where Φ is the torsional angle, and n defines the number of minima or maxima between 0 and 2π . The constant V_n determines the height of the potential energy barrier between torsional states.

All these terms make local contributions to the calculated potential energy. As seen in the figures, molecules are treated as consisting of balls (the atoms) connected by springs (the bonds). The building blocks in molecular force fields are atoms. The electrons are not treated as individual particles and no electronic details, which would require a quantum mechanical treatment,

are included. Additionally the quantum aspects of nuclear motion are neglected and the dynamics of the atoms in the molecule are treated by classical mechanics.

Non-bonded interactions

In common molecular force fields the non-bonded interactions include electrostatic forces and van der Waals forces.

- 4) The fourth term describes the electrostatic forces arising between atoms carrying a ionic charges, q_i and q_j : $\frac{q_i q_j}{r_{ij}}$. Charge-charge interactions between positive and negative ions are called salt bridges, which play a significant role in protein structure stabilization. Since substitution of basic residues for acidic residues changes the charge from positive to negative, such changes are extremely destabilizing when they occur in the interior of the protein. They tend to be more acceptable on the protein surface where the charged residues interact with polar water molecules and charged solutes.
- 5) The fifth term of the force field describes van der Waals forces: $\sum_i \sum_j (\frac{A_{ij}}{r_{ij}^{12}} - \frac{B_{ij}}{r_{ij}^6})$. The movement of the electrons around the atomic nucleus creates an electric dipole moment. This dipole polarises neighbouring atoms, which results in a short-range attractive force between the non-bonded atoms (i, j).

The attractive part is described by: $-\frac{B_{ij}}{r_{ij}^6}$. Conversely, at short ranges a repulsive force between the electrons of the two atoms arises (Fig. 17). The radius at which the repulsive force begins to increase sharply is called the van der Waals radius.

The repulsive part of the energy is described by: $\frac{A_{ij}}{r_{ij}^{12}}$. Steric interactions arise when the van der Waals spheres of two non-bonded atoms are approach and interpenetrate (Fig. 18). The parameters A_{ij} and B_{ij} depend on the types of the involved atoms. This description of van der Waals forces is frequently referred to as a Lennard-Jones potential.

The equilibrium geometry of a molecule (with respect to bond lengths, angles, non-overlapping van der Waals spheres, etc.) describes the coordinates of a minimum on the potential energy surface. The problem is then reduced to determining the energy minima on this surface (Fig. 19).

The minimum of the potential energy function corresponds to the equilibrium geometry of the molecule.

An advantage of the molecular force fields method is the speed with which calculations can be performed, enabling its application to large biomolecules. With even moderate computer power, the energies of molecules with thousands of atoms can be optimized. This facilitates the molecular modelling of proteins and nucleotide acids, which is currently done by most pharmaceutical companies. There are different methods for the optimization the energy, such as: simulated annealing and conjugate gradients.

Fig. 17 Potential energy function for van der Waals interaction.

Fig. 18 Steric hindrance may result from overlapping of the van der Waals spheres associated with the residues. This leads to strong repulsive forces.

Fig. 19 The potential energy function of a molecule depends on the coordinates of its atoms.

Energy Optimization by Simulated Annealing

Simulated Annealing is an effective and general form of energy optimization. It is useful in finding the global minimum in the presence of several local minima (Agostini *et al.*, 2006; Cerny, 1985). The term annealing refers to the thermal process for obtaining low energy states of a solid in a heat bath. The annealing process consists of two steps: First the temperature of the heat bath is increased until the solid melts. Then the temperature of the heat bath is decreased slowly. If the melt is cooled slowly, large single crystals, representing the global minimum energy state, grow. Rapid cooling produces a disordered solid trapped in a local minimum energy state.

In statistical thermodynamics, the probability of a physical system being in the state with energy E_i at temperature T is given by the Boltzmann distribution:

$$p(E_i) = \frac{1}{Z} \cdot e^{-\frac{E_i}{k_B T}}$$

The parameter k_B is the Boltzmann constant that relates temperature to energy ($E \approx k_B T$). The function Z is the canonical partition function, which is the summation over all possible states, j , with energy E_j at temperature T :

$$Z = \sum_j e^{-\frac{E_j}{k_B T}}$$

Here we use the potential energy $U(r)$ of the molecular force field. Thereby, the parameter r is the set of all atomic coordinates, bond angles and dihedral angles. The probability of observing a particular molecular conformation is given by the above Boltzmann distribution. The probability of molecular transition from state r_k to state r_l is determined by the Boltzmann distribution of the energy difference, $\Delta E = U(r_k) - U(r_l)$, between the two states:

$$P = e^{-\frac{\Delta E}{k_B T}}$$

The different molecular configurations are given by different values of bond lengths, angles, dihedral angles, and non-bonded interactions in the protein. The states are modified by random modifications of these parameters. (*Mostly computational algorithms for pseudo-random number generators are used*). For example, consider random changes to a dihedral angle (Fig. 20). Then examine the energy associated with the resulting atom positions to decide whether or not to accept each considered move. T is a control parameter called *computational temperature*, which controls the magnitude of the random perturbations of the potential energy function. At high temperatures, large modifications of the molecular configuration, resulting in large changes in energy, are preferred. (At high T the Boltzmann distribution exhibits a uniform preference for all states, regardless of their energy). As T is lowered, the system responds mainly to small changes in the potential energy, and performs a fine search in the neighborhood of the already determined minimum to find a better minimum. When T approaches zero, only the states with lowest energies have nonzero probabilities of occurrence. At the initial high temperature, large conformational changes of the molecule are allowed. But as the temperature is decreased, the conformation of the molecule becomes trapped in an energy minimum (Fig. 21). The probabilities of uphill moves ($\Delta E > 0$) in the energy potential function

Fig. 20 The dihedral angle of the side chain of ILE 183 is changed randomly. Thereby results a change of the energy of the protein.

(of the molecular force field) are more likely at high temperature than at low temperature. Simulated annealing allows uphill moves in the energy potential function in a controlled fashion: It attempts to avoid a greedy movement to the next local minima by occasionally accepting a worse solution. This procedure is called the Metropolis criteria. Simulated annealing is a variant of the Metropolis algorithm, where the temperature is changing from high to low (Kirkpatrick *et al.*, 1983). The probability of accepting a conformational change that increases the energy decreases exponentially with the difference in the energies, ΔE , in the respective conformations.

The simulated annealing is basically composed of two stochastic processes: one process for the generation of a conformational change (for example a dihedral angle is modified) and the other for the acceptance of or rejection of the new conformation. The *computational temperature* is responsible for the correlation between the generated and the initial conformation.

In a typical simulated annealing optimization, T starts high and is gradually decreased according to the following algorithm:

```

Initialize the molecular configuration:  $r = r_{\text{init}}$ ;
Assign a large value to temperature:  $T = T_{\text{max}}$ ;
Repeat:
  Repeat:
    The configuration  $U(r)$  is modified by random perturbation:  $r = r + \Delta r$ ;
    The resulting energy difference is evaluated:  $\Delta E = U(r + \Delta r) - U(r)$ ;
    If  $\Delta E < 0$  then: keep the new configuration;
    otherwise: accept the new configuration with a probability:  $P = e^{-\frac{\Delta E}{k_B T}}$ ;
  until the number of accepted transitions is below a predefined threshold level.
Set:  $T = T - \Delta T$ ;
until  $T$  is small enough.
End
  
```

As the temperature decreases, uphill moves become more and more unlikely, until there are only downhill moves, and the molecular configuration converges (in the ideal case) to the equilibrium conformation. The size (ΔT) of the cooling steps for T is critical to the efficiency of simulated annealing. If T is reduced too rapidly, a premature convergence to a local potential minimum may occur. In contrast, if the step size is too small, the algorithm converges very slowly to a global minimum.

Model Verification

The dihedral angle, ω , of the protein backbone is restricted due to the planarity of the amide bond (C and N) and the hybridization of the involved atomic orbitals (Fig. 22). From this results a resonance structure with partial double binding and a permanent dipole moment (with negatively charged oxygen). Therefore rotation around ω requires a large amount of energy (80 kJ/mol). The values of the dihedral angles ϕ and ψ are restricted by the steric hindrance between the atoms of neighbouring peptide bonds and side chain atoms.

The Ramachandran plot shows the statistical distribution of the combinations of the backbone dihedral angles ϕ and ψ . In theory, the allowed regions of the Ramachandran plot show which values of the Phi/Psi angles are possible for an amino acid, X, in

Fig. 21 The potential energy function with local and global minima depending on the molecule conformation.

Fig. 22 Definition of the protein backbone dihedral angles ω , ψ and ϕ .

a ala-X-ala tripeptide (Ramachandran *et al.*, 1963). In practice, the distribution of the Phi/Psi values observed in a protein structure can be used for structure validation (Ramakrishnan *et al.*, 2007). The Ramachandran plot visualizes energetically allowed and forbidden regions for the dihedral angles. For poor quality homology models, many dihedral angles are found in the forbidden regions of the Ramachandran plot. Such deviations usually indicate problems with the structure.

Fig. 23 shows the Ramachandran plot of the homology model of the amino acid sequence of orotidine 5'-monophosphate decarboxylase. The plot is a visualization produced by Swiss-PDB viewer, and colors were added after the plot was generated. The dihedral angles of amino acid residues appear as crosses in the plot. The blue and red regions represent the favoured and allowed regions. The blue regions correspond to conformations where there are no steric clashes in the model tripeptide. These favoured regions include the dihedral angles typical of the alpha-helical and beta-sheet conformations. The orange areas correspond to conformations where atoms in the protein come closer than the sum of their van der Waals radii. These regions are sterically forbidden for all amino acids with side chains (the exception is glycine which has no side chain). In Swiss-PDB viewer, the Ramachandran plot can be used to interactively modify the Phi/Psi angles of an amino acid

A number of freely available software tools can be used to analyze the geometric properties of homology modelling results. These model assessment and validation tools are generally of two types: Programs of the first category (PROCHECK and WHATCHECK) perform symmetry and geometry checks (including bond lengths, bond angles, and torsion angles) and consider the influence of solvation. Those in the second category (VERIFY3D and ProSA) check the quality of the sequence to structure match and assign a score for each residue (Table 5).

ANOLEA (Atomic Non-Local Environment Assessment) is a server that performs energy calculations on a protein chain, by use of a distance-dependent knowledge-based mean force potential, derived from a database (Melo *et al.*, 1997). Thereby the Non-Local Environment (NLE: defined as all the heavy atoms, within an Euclidean distance of 7 Å and that belong to amino acids that are more distant than 11 residues) of each heavy atom in the molecule is evaluated.

Fig. 23 Distribution of the amino acid Phi/Psi angles in the orotidine 5'-monophosphate decarboxylase.

Table 5 Software packages that can be used to evaluate the quality of the geometry and sequence to structure fitness of a homology-based model

Name	Method	Web address
PROCHECK	Checks the stereo-chemical quality	http://www.ebi.ac.uk/thornton-srv/software/PROCHECK/
WHATCHECK		http://swift.cmbi.ru.nl/gv/whatcheck/
ProSA	Checks the fitness of sequence to structure	https://prosa.services.came.sbg.ac.at/prosa.php
VERIFY3D		http://services.mbi.ucla.edu/Verify_3D/
ANOLEA	Energy calculations	http://melolab.org/anolea/

Fig. 24 shows the final homology model of the amino acid sequence of orotidine 5'-monophosphate decarboxylase. The target structure (represented by the ball-and-stick diagram) is superimposed on that of a template structure (represented by the ribbon diagram).

In conclusion it should be noted that a protein model is a tool that helps to interpret biochemical data. Models can be inaccurate or even completely wrong.

Applications of Homology Modelling in Human Biology and Medicine

Today homology modelling is one of the most common techniques used to build accurate structural models of proteins, and is used for rationalizing experimental observations. It is widely used in structure based drug design, and the study of inter-individual differences in drug metabolism (Cavasotto and Abagyan, 2004). Further applications include: (a) designing site-directed mutants to test hypotheses about protein function; (b) identification and structural analysis of small molecule binding sites for ligand design and search; (c) design and improvement of inhibitors for an enzyme based on its predicted substrate or product binding sites; (d) prediction and analysis of epitopes; (e) modelling of substrate specificity; (f) protein-protein docking simulations (see Table 6).

Fig. 24 Snapshot of the Swiss-PDB viewer showing the result of the homology modelling procedure.

Table 6 A selected list of homology modelling projects in medicine

Homology modelling projects	Authors
<i>P. falciparum</i> DHFR enzyme inhibitors	Adane and Bharatam (2008)
Beta2-adrenergic receptor	Costanzi (2008)
<i>Apis mellifera</i> nicotinic acetylcholine receptor	Rocher <i>et al.</i> (2008)
Histone deacetylases (HDACs)	Wang <i>et al.</i> (2005)
Human β 2-adrenergic G protein coupled receptor	Cherezov <i>et al.</i> (2007)
Serotonin 5-HT _M receptor	Nowak <i>et al.</i> (2006)
Anti-CD34 Monoclonal Antibody	Hou <i>et al.</i> (2008)
Human GAD65	Capitani <i>et al.</i> (2005)
Acetyl CoA carboxylase	Zhu <i>et al.</i> (2006)
Human serum carnosinase	Vistoli <i>et al.</i> (2006)
Cannabinoid receptor-2	Diaz <i>et al.</i> (2009)
C-terminal domain of human Hsp90	Sgobba <i>et al.</i> (2008)
Cytochrome sterol 14 alpha demethylase	Zhang <i>et al.</i> (2010)
Human adenosine A2A receptor	Michielan <i>et al.</i> (2008)
Adenosine A2a receptor complex	Katritch <i>et al.</i> (2010)
Melanin concentrating hormone receptor	Cavasotto <i>et al.</i> (2008)
Carbonic Anhydrase IX	Tuccinardi <i>et al.</i> (2007)
Brain lipid binding protein	Xu <i>et al.</i> (1996)
Human dopamine receptors	Wang <i>et al.</i> (2010)
Dopamine D ₃ receptor	Cui <i>et al.</i> (2010)
Alpha-1-adrenoreceptors	Li <i>et al.</i> (2008)
Human P-glycoprotein	Domicieva and Biggin (2015)
G Protein-coupled Estrogen Receptor	Bruno <i>et al.</i> (2016)
Trace amine-associated receptor 2	Cichero and Tonelli (2017)
Histamine Receptors	Strasser and Wittmann (2017)
Human tyrosinases	Hassan <i>et al.</i> (2017)
TSP0 protein	Bhargavi <i>et al.</i> (2017)
Cajanus cajan Protease Inhibitor.	Shamsi <i>et al.</i> (2017)
African horse sickness virus VP7 trimer	Bekker <i>et al.</i> (2017)
Cytochrome bc1 complex binding	Sodero <i>et al.</i> (2017)
Human P2X7 receptor	Caseley <i>et al.</i> (2017)

The structures of medically relevant proteins involved in malaria, nicotinic acetylcholine receptor, bacteria inhabiting the gastrointestinal tract, anticancer drugs, hematopoietic stem/progenitor cell selection, autoimmunity and many more, have been determined by homology modelling (Table 6).

Introduction

Recent successes in proteomics have led to a spate of sequence data. This data can benefit society only if one can decipher the functions and malfunctions of proteins, and this requires their structures, in addition to sequence information (Koga *et al.*, 2012; Bhattacharya, 2009; Grishin, 2001). Currently, almost a thousand fold gap exists between the number of known protein sequences in UniProtKB (~90 million sequences) (Boutet *et al.*, 2016) and the number of corresponding structures in the Protein Data Bank (PDB) (~0.13 million structures) (Berman *et al.*, 2007), as shown in Fig. 1. The urgency of determining protein structures is further underscored by various drug discovery endeavours. Protein structure elucidation from sequence is among the top hundred outstanding problems in modern science (Blundell, 1996).

Despite major developments in the field of experimental structure determination using X-ray crystallography, NMR and cryo-EM techniques (Shi, 2014; Chapman *et al.*, 2011; Raman *et al.*, 2010; Fernandez-Leiro and Scheres, 2016; Doerr, 2015), the mounting gap between known protein sequences and structures has created the need for reliable computational protein structure prediction methodologies (Marks *et al.*, 2012; Petrey and Honig, 2005; Baker and Sali, 2001). In the post-Anfinsen era, the field of protein structure prediction has made substantial progress, as chronicled through the biennial Critical Assessment of Techniques

Fig. 1 A comparison of the annual growth rates of available protein sequences in UniProtKB and available protein structures in Protein Data Bank. Data source: UniProtKB and PDB.

for Protein Structure Prediction (CASP) experiments (Moult *et al.*, 2014), and by a continuous automated model evaluation with CAMEO (Haas *et al.*, 2013), among others.

The field of protein tertiary-structure prediction originated in physics-based molecular mechanics and dynamics (*ab initio* modeling) approaches (Pearlman *et al.*, 1995; Lindorff-Larsen *et al.*, 2012), but its success was restricted to small proteins because of its compute intensive nature (Kulik *et al.*, 2012; Lindorff-Larsen *et al.*, 2011; Jayaram *et al.*, 2006; DasGupta *et al.*, 2015). However, *ab initio* approaches offer the potential of predicting new folds (Huang *et al.*, 2016; Klepeis *et al.*, 2005; Mittal *et al.*, 2010). Subsequently, advances in bioinformatics, and data mining in particular, led to the development of some extremely popular knowledge-based methods (comparative modeling) which utilize information ingrained in experimentally solved protein structures (Ginalski, 2006; Shenoy and Jayaram, 2010). The success of comparative modeling approaches is limited by the availability of known reference structures, and this precludes discovery of new folds. Also, owing to the nature of the methodology adopted, comparative modeling approaches are not of much help in providing insights into the physico-chemical mechanism of protein folding (Dill and MacCallum, 2012; Garcia and Onuchic, 2005). A jump in the accuracy of protein structure prediction was realized with the development of integrated approaches (hybrid methods) that combine physical and knowledge-based methods (Zhang, 2008; Kim *et al.*, 2004; Jayaram *et al.*, 2014).

In this article, we discuss various methods for implementing *ab initio* approaches to protein structure prediction, mostly for small globular proteins. *Ab initio* structure prediction has several names such as *de novo* prediction, physics-based prediction, free modeling, *etc.*, which are used interchangeably. We will use the term *ab initio* prediction to encompass these diverse endeavours. Before we delve into the methodological details, we introduce here some basic concepts and assumptions important in protein structure prediction.

Ab initio Protein Structure Prediction

The pioneering work in the field molecular dynamics simulation by Karplus, Levitt and their coworkers laid the foundation for *ab initio* approaches (McCammon *et al.*, 1977; Levitt and Warshel, 1975; Levitt, 1976; Levitt and Sharon, 1988; Scheraga *et al.*, 2007). The field has been further accelerated by the landmark work on the folding of villin headpiece subdomain by Kollman and coworkers (Duan and Kollman, 1998). The efforts of Shaw and coworkers, with their special purpose Anton computer, which was designed to fold proteins in real time, have given a big boost to *ab initio* protein folding (Lindorff-Larsen *et al.*, 2011, 2012). Despite the recent successes enjoyed by *ab initio* approaches, a few road-blocks are yet to be circumvented, such as the methodology required for sampling and accurately identifying a native fold from the astronomical conformational space of larger proteins.

The axioms implicit in *ab initio* approaches, initially proposed by Anfinsen (1973) are that (i) the amino acid sequence of a protein uniquely determines its tertiary structure, and that (ii) the native conformation of a protein sequence corresponds to its global free-energy minimum. For *ab initio* protein structure prediction methods, it is obligatory to have a scoring function (typically a physics-based energy function) and a sampling method for searching the conformational space. In this section, we discuss some scoring functions used in *ab initio* approaches, and the most commonly used strategies for conformational sampling.

Scoring Functions

Essentially a scoring function has to mimic a free energy function. Scoring functions have to capture structures with minimum free energies. Noting that free energy which combines both enthalpy and entropy, is a statistical quantity which depends on an ensemble of structures and not a mechanical quantity which is calculable even for a single structure, formulating a scoring function to rank conformations free energetically is a difficult task. Based on their underlying principles, scoring functions, may be classified into two categories, *viz.* physics-based and statistics-based. Physics-based scoring functions are mathematical models that describe inter-atomic interactions (Duan and Kollman, 1998; Weiner *et al.*, 1984; Hagler and Lifson, 1974; Cornell *et al.*, 1995; Jorgensen and Tirado-Rives, 1988; Brooks *et al.*, 1983). Statistics-based functions, also known as knowledge-based functions or empirical-energy functions, are statistical models that are derived from various properties of native protein structures (Jayaram *et al.*, 2006; DasGupta *et al.*, 2015; Skolnick *et al.*, 1997; Samudrala and Moult, 1998; Shen and Sali, 2006). Usually, physics-based scoring functions account for bonded interactions *via* terms that describe bond lengths, bond angles, dihedral angles, *etc.*, and non-bonded interactions *via* terms that include van der Waals interactions, electrostatic interactions, hydrophobic effects, *etc.* Knowledge-based functions account for solvent accessibility, secondary structural preferences, torsion angle preferences, residue-residue pairwise potentials, packing fraction, *etc.*, and are derived from experimentally solved protein structures.

Physics-based functions

Ideally, atomic interactions can be best described using quantum mechanical (QM) calculations, and columbic interactions among the elementary particles involved (Kulik *et al.*, 2012). However, the potential use of quantum mechanical calculations in *ab initio* protein structure prediction cannot be explored, even for small proteins, because of their extremely compute intensive nature. Physics-based functions typically adopt the Born-Oppenheimer approximation and molecular mechanics (MM) instead,

Table 1 A list of force fields/software suites that implement physics-based energy scoring functions for *ab initio* protein structure prediction

Force field/software suite	Basic strategy for sampling and scoring	Availability
CHARMM	Molecular dynamics (MD)	https://www.charmm.org
AMBER	Molecular dynamics (MD)	http://www.ambermd.org
GROMOS	Molecular dynamics (MD)	http://www.gromos.net
OPLS	Molecular dynamics (MD)	http://zarbi.chem.yale.edu
ENCAD	Energy Calculation & Dynamics	http://depts.washington.edu
UNRES	Conformational space annealing (CSA)	http://www.unres.pl

giving rise to continual development of MM force fields, wherein the system (protein) may be an all-atom model or a coarse-grained model system. Some of the most commonly used all-atom model force fields (and software suites which adopt the MM force fields) include CHARMM (Chemistry at HARvard Macromolecular Mechanics) (Brooks *et al.*, 1983), AMBER (Assisted Model Building and Energy Refinement) (Pearlman *et al.*, 1995; Weiner *et al.*, 1984; Cornell *et al.*, 1995), OPLS (Optimized Potentials for Liquid Simulations) (Jorgensen and Tirado-Rives, 1988), and GROMOS (GROningen Molecular Simulation) (Brunne *et al.*, 1993; Van Der Spoel *et al.*, 2005). Additionally, CHARMM, AMBER and GROMOS also include united atom model force fields with a higher computational efficiency. These model systems differ from each other in their atom-type definitions, the force-field functional forms, and the parameters they use to account for inter-atomic interactions. Coarse-grained model systems include UNRES (UNited RESidue) (Liwo *et al.*, 1999), TOUCHSTONE (Skolnick *et al.*, 2003; Kihara *et al.*, 2001) and Martini (Marrink *et al.*, 2007). The UNRES coarse grained model system accounts only for two interaction sites, namely united side-chain and united peptide group, per residue, which offers ~1000 to 4000-fold time speed-up compared to all-atom model systems. The TOUCHSTONE coarse-grained model implements a reduced lattice-based model, which is used with replica exchange Monte Carlo approaches to account for short range interactions, local conformational stiffness, long range pairwise interactions, hydrophobic, and electrostatic interactions. The Martini coarse grain force field implements the mapping of four heavy atoms for individual coarse grained interaction, termed as bead. In Martini force field, four major bead categories are defined *viz.* charged, polar, non-polar and apolar. Energy Calculation and Dynamics (ENCAD) is another set of energy parameters designed for simulations of macromolecules with solvation, which focuses on energy conservation and reduces calculations by applying a distance cutoff (truncation) for nonbonded interactions (Levitt *et al.*, 1995). Table 1 summarizes some of the physics-based scoring functions along with their availability in the public domain.

Knowledge-based functions

Structural features and interaction patterns, derived from non-redundant datasets of experimentally determined high-resolution protein structures, are used for formulating various knowledge-based scoring functions. Knowledge-based scoring functions are also called statistics-based scoring functions because different statistical parameters are derived from the frequencies of interactions in experimentally determined structures that are favourable or seen in native proteins. These features and patterns may include pairwise interactions of residues, solvent accessible surface area, exposure of hydrophobic residues on the protein surface, packing density of protein secondary structural element and tertiary structures, etc. (Yang and Zhou, 2008; Laskowski *et al.*, 1993; Wiederstein and Sippl, 2007; Eisenberg *et al.*, 1997; Benkert *et al.*, 2009; Zhou and Skolnick, 2011). The probability of structural interaction patterns can be transformed to an energy function by implementing an inverse Boltzmann approach with a known probability reference state (derived from the reference dataset) as shown in Eq. (1).

$$\Delta E = -k_B T \ln \left\{ \frac{P_{obs}}{P_{ref}} \right\} \quad (1)$$

where, k_B is Boltzmann's constant, T is the thermodynamic temperature, P_{obs} is the probability of the predicted (observed) features, and P_{ref} is the probability of the reference feature, derived from the experimental dataset. The application of the inverse Boltzmann law assumes the mutual independence of the observed features and patterns, and their distribution in accordance with Boltzmann's Law. However, the mutual independence of the derived features is a severe approximation, and thus was not considered in early studies.

Statistics-based functions show a tendency to be skewed with respect to varying sizes of proteins and, thus may sometimes be misleading if they are not thoroughly validated on a large dataset of proteins of diverse sequence lengths. The selection and curation of the reference dataset, which is used for deriving structural features and interaction patterns, determines the accuracy of knowledge-based scoring functions. In Table 2, some successful knowledge-based scoring functions are listed along with their availability.

Physics and knowledge-based integrated functions

Owing to the individual limitations of physics-based and knowledge-based scoring functions, integrated scoring functions have been developed that couple the two approaches to improve prediction accuracies. These combined approaches extract certain

Table 2 A list of programs that implement knowledge-based potentials for *ab initio* protein structure prediction

features and patterns from experimentally-solved protein structures, and implement them in physics-based energy scoring functions to identify correctly folded conformations (Davis *et al.*, 2007; Mishra *et al.*, 2013; Colovos and Yeates, 1993; Mishra *et al.*, 2014; Ray *et al.*, 2012; Singh *et al.*, 2016; Melo and Feytmans, 1998).

Conformation Sampling

Classical protein folding studies on small proteins implemented physics-based potential functions (force fields) for use in molecular dynamics (MD) simulations which provided insights into the molecular mechanisms of folding pathways. The increasing quality of the energy functions is a major strength of MD approaches, but purely MD based protein folding is feasible only for small proteins (less than 100 amino acid residues), unless simplified models are used. Continuously increasing compute power and resources offer the possibility of performing long (milliseconds and longer) MD simulations in order to explore the mechanisms of folding and unfolding of even larger proteins. For instance, MD algorithms implemented on graphics processing units (GPUs) have significantly contributed to accelerating such calculations. Also, the development of enormously parallel clusters (e.g., BlueWaters) (Mendes *et al.*, 2014) and special-purpose supercomputers (e.g., Anton) (Shaw *et al.*, 2014) has created opportunities for performing micro to millisecond simulations on biomolecules (Lindorff-Larsen *et al.*, 2012; Zhang, 2008). Another frequently used approach in molecular dynamics is Replica Exchange Molecular Dynamics (REMD), which implements multiple parallel simulations for the same biomolecule, with each simulation (termed a replica) running at a different temperature within a defined temperature scale. These parallel simulations may exchange their temperatures at intervals with non-zero probability (Sugita and Okamoto, 1999; Sugita *et al.*, 2000). The efficiency of REMD is strongly dependent upon the number of replicas and the range of selected temperatures. REMD approaches can address the multiple local minima problem more efficiently than conventional molecular dynamics simulations, which are carried out at fixed temperature. Further details of REMD-algorithm based approaches can be gleaned from more specific review articles (Zhou, 2007; Kar *et al.*, 2009; Sugita *et al.*, 2012; Chen *et al.*, 2015). However, the optimal use of computational resources for achieving consistent success for all types of proteins is highly dependent upon the accuracy of the physical model/force field.

In this section, we briefly summarize the chronological progress of the field of *ab initio* conformational sampling and the various force fields which have been implemented. In the protocol advanced by Beveridge and coworkers, medium accuracy structures of small proteins are identified by enabling the MD simulation to escape from meta-stable local minima by using an integrated energy function adopted from AMBER. The integrated energy function includes a solvent dielectric polarization function, van der Waals interactions, and cavitation effects, and uses a Monte Carlo simulated-annealing search scheme (Liu and Beveridge, 2002). The *ab initio* method of Gibbs *et al.* predicted structures of small proteins (up to 38 residues) to within 3 Å RMSD, allowing only the rotatable backbone dihedral angles (ϕ and Ψ) to change, considering the side chains as fixed, by implementing a physicochemical feature-based force field to evaluate the energies (Gibbs *et al.*, 2001). Scheraga and coworkers implemented a global optimization procedure based on a modified united-residue force field (UNRES) and conformational space annealing, with considerable success for helical proteins (Liwo *et al.*, 1999). Rose and coworkers proposed LINUS, a Monte Carlo simulation-based tool, which mainly focused on the impact of steric interactions and conformational entropy, with a simplified scoring function accounting for hydrophobic interactions and hydrogen bonds. Cubic or tetrahedral lattice representations have been used previously for reducing the size of the conformational space (Srinivasan *et al.*, 2004). Skolnick and coworkers proposed a face-centered cubic lattice model accounting for hydrophobic interactions, hydrophobic-polar repulsive interactions, and polar-polar interactions (Pokarowski *et al.*, 2003). Jayaram *et al.* proposed an *ab initio* methodology (christened *Bhageerath*) based on physics-based potentials integrated with biophysical filters, and predicted medium accuracy model structures (3–6 Å RMSD) for small proteins (Jayaram *et al.*, 2006; Jayaram *et al.*, 2012). Recently, fragment library approaches have been used to generate initial models for performing simulations, which circumvent the earliest steps in folding (such as local structure formation). Fragment libraries may be directly extracted from experimentally solved structures or on the basis of various features of amino acids. A small set of structural fragments is sufficient to accurately model protein structures, as demonstrated by Levitt and coworkers, who used different sized libraries with simulated-annealing k-means clustering (Kolodny *et al.*, 2002), and later by Jayaram and coworkers using tripeptide based backbone dihedral angle preferences derived from non-redundant experimental structures for predicting the tertiary structure of small proteins (DasGupta *et al.*, 2015).

Automation of *Ab initio* Structure Prediction

The different approaches for *ab initio* protein tertiary-structure prediction, as implemented in popular software/tools, are discussed here. It may be noted that the list of servers/ software/ tools presented here is not exhaustive, and does not cover all the available *ab initio* methodologies, for which the reader's indulgence is sought. Methodologies are listed in chronological order of their development and availability to the scientific community. Additionally, a brief summary of the various *ab initio* methods is provided in a tabular form for a quick reference.

Rosetta

This is an *ab initio* tertiary-structure prediction methodology for small proteins implemented as a web server. It is also made available for local installation on linux based computers, although, the standalone version requires huge compute resources and, single CPU machines may take ages to produce a structural model. The web server is more popular, and can predict a model structure in a few days, depending upon the queue. Initial versions of Rosetta implemented a simplified simulated annealing protocol for performing fragment assembly of peptide 9-mers and 3-mers derived from protein structures having similar local sequences, using Bayesian scoring functions to predict protein tertiary structures of small proteins (Das and Baker, 2008). A general workflow of the Rosetta *de novo* methodology is shown in Fig. 2. Since the Rosetta method is restricted to small proteins, a hybrid methodology has been developed that integrates the *ab initio* (Rosetta method) and homology-based methods in the Robetta server (Kim *et al.*, 2004). The integrated approach has achieved considerable success in the field of protein structure prediction.

QUARK

QUARK performs *ab initio* prediction using small fragment structural libraries of up to 20 amino acid residues, followed by replica-exchange Monte Carlo simulations with an atomic-level knowledge-based scoring function (Xu and Zhang, 2012). For a given target protein, secondary structure prediction is performed with PSSpred, (Yan *et al.*, 2013) and a sequence profile generated from a PSI-BLAST multiple sequence alignment (Altschul *et al.*, 1997). Further, neural networks are implemented for predicting residue-specific

Fig. 2 A workflow of Rosetta methodology for performing *ab initio* protein tertiary structure prediction for a given target protein sequence. Based on methodology explained in Das, R., Baker, D., 2008. Macromolecular Modeling with Rosetta. Annual Review of Biochemistry, 77(1), 363–382.

Fig. 3 A simplified flowchart of QUARK *ab initio* protein tertiary structure prediction. Based on methodology explained in Xu, D., Zhang, Y., 2012. *Ab initio* protein structure assembly using continuous structure fragments and optimized knowledge-based force field. *Proteins: Structure, Function and Bioinformatics*, 80(7), 1715–1735.

solvent accessibilities, backbone dihedral angles (ϕ and Ψ), and β -turn positions. The sequence profile, predicted secondary structure, solvent accessibilities, backbone dihedral angles, and β -turn positions are used for generating structural fragments of variable lengths (up to 20 residues) for segments of target sequence. The full length model structures are further scanned to filter out similar structures using SPICKER, followed by full atomic refinement with a knowledge-based scoring function (Zhang and Skolnick, 2004a). A workflow of QUARK *ab initio* prediction is shown in Fig. 3. Since success of protein structure prediction using the QUARK method is restricted to only small proteins (up to 200 amino acid residues), the QUARK *ab initio* methodology has been integrated with comparative-modeling based fold recognition and threading approaches in the I-TASSER software suite (Yang *et al.*, 2014) in order to allow the prediction of larger protein structures with improved efficiency.

TOUCHSTONE

TOUCHSTONE performs *ab initio* prediction by implementing a threading approach, which is based on secondary and tertiary structural parameters derived from experimentally solved protein structures (Skolnick *et al.*, 2003; Kihara *et al.*, 2001). These parameters include consensus contacts and local secondary structures at fragment levels. The conformational space is explored with the help of replica-exchange Monte Carlo to generate a reduced lattice-based protein model. Further, decoy structures are clustered and scored with a knowledge-based residue-specific heavy-atom pair potential to select representative structures. Confidence in the prediction accuracy is evaluated based on number of predicted contacts and the number of simulated contacts from the replica-exchange Monte Carlo simulations. The methodology showed considerable success on a validation dataset of 65 small proteins (up to 150 amino acid residues) in predicting model structures within 6.5 Å RMSD of their respective native structures. The updated version of the methodology (released two years later) implemented different short-range and long-range knowledge-based potentials and this resulted in improved predictions.

Bhageerath

Bhageerath is an energy-based software suite for restricting the conformational search space for small globular proteins (Jayaram *et al.*, 2006; Levitt *et al.*, 1995). The automated protocol of Bhageerath spans eight different modules that integrate physics-based potentials with knowledge-based biophysical filters, and produces ten representative model structures for an input protein sequence and its corresponding secondary structure. The performance of Bhageerath was benchmarked against homology-based methods and found to perform consistently better for predicting medium accuracy model structures for small globular proteins (up to 100 amino acid residues). The first module generates a coarse-grained model given the input target sequence and predicted secondary structure in the form of helices, strands and coils. Backbone dihedral angles (ϕ and Ψ) based conformational sampling of the amino acid residues representing coil region is performed in the second module to generate trial structures. Seven dihedral angles from each stretch of residues representing coil region are selected. For each selected dihedral angle, two preferred values for ϕ and Ψ are adopted from experimental protein structures which results into 2^7 conformation (128 conformations per loop).

Fig. 4 A flowchart of Bhageerath *ab initio* protein structure prediction methodology. Based on methodology explained in Jayaram, B., Bhushan, K., Shenoy, S.R. *et al.*, 2006. Bhageerath: An energy based web enabled computer software suite for limiting the search space of tertiary structures of small globular proteins. *Nucleic Acids Research*, 34(21), 6195–6204.

For an individual stretch of amino acid residues representing a coil region in the predicted secondary structure, this module generates 128 different conformations. When the number of coil regions (excluding N-terminal and C-terminal coil regions) in the predicted secondary structure increases, the number of generated conformations increases exponentially. For instance, for a protein sequence with ‘*n*’ number of secondary structural elements in the predicted secondary structures (number of helices + number of strands), a total of $128^{(n-1)}$ trial conformations are generated. In the third module, the trial conformations are scanned through biophysical filters *viz.* persistence length and radius of gyration (Narang *et al.*, 2005), to exclude improbable conformations. Steric clashes and overlaps are rectified in the fourth module using Monte Carlo sampling in the backbone dihedral angle space. Further, an implicit solvent energy minimization with a distance dependent dielectric and side chain optimization is performed in the fifth module. The sixth module performs energy ranking based on an all-atom energy-based empirical scoring function, selecting the top 100 lowest energy structures (Narang *et al.*, 2006). A protein regularity index, which checks the compatibility of backbone dihedral angles of predicted conformations over experimentally solved protein structures (Thukral *et al.*, 2007), is implemented in the next module to reduce the number of candidate structures. Finally, in the eighth module, topologically equivalent structures are screened out and the top 10 structures are selected based on solvent surface accessibility (lower values are preferred), ranked and provided to the user. A flowchart of the automated Bhageerath pipeline is depicted in Fig. 4. The Bhageerath *ab initio* methodology can perform structure prediction for small proteins (up to 100 amino acid residues), and is integrated with homology-based methods in the BhageerathH⁺ software suite (Jayaram *et al.*, 2012, 2014; Singh *et al.*, 2016; Dhingra and Jayaram, 2013; Kaushik and Jayaram, 2016) to perform reliable structure prediction for large proteins.

ASTRO-FOLD

ASTRO-FOLD performs *ab initio* protein tertiary-structure prediction based on a combinatorial and global optimization framework (Klepeis and Floudas, 2003). The initial version of ASTRO-FOLD implemented a hierarchical method that integrated an all-atom energy function, global optimization algorithm, conformational space annealing, and MD simulations in dihedral angle conformational space. More recently, an updated version of ASTRO-FOLD has been released (christened ASTRO-FOLD 2.0) that predicts the secondary structure of a target protein using various statistical potentials, followed by contact prediction, and loop prediction (Subramani *et al.*, 2012). These predictions are used for deriving various restraints, such as dihedral angle and C α –C α distance restraints. The restraints are used for further conformational sampling using a combinatorial and global optimization algorithm. A simplified workflow of ASTRO-FOLD 2.0 is shown in Fig. 5.

RaptorX-FM

Probabilistic graphical models are used for deriving relationships among backbone dihedral angles, sequence profiles, and secondary structural elements, which results in more accurate backbone dihedral angle prediction and more efficient conformational sampling. The method performs better on all-alpha proteins, with up to 150 amino acid residues, and small all-beta proteins, with up to 90 amino acid residues. For conformation sampling, the probabilistic graphical models, Conditional Random Fields (CRF), which utilize a linear relationship between backbone dihedral angles and the sequence profile, and Conditional Neural Fields (CNF), which employ a neural-network based nonlinear relationship between backbone dihedral angles and the sequence profile, are coupled with

Fig. 5 A workflow of ASTRO-FOLD 2.0 for *ab initio* protein structure prediction. Based on methodology explained in Subramani, A., Wei, Y., & Floudas, C.A., 2012. ASTRO-FOLD 2.0: An enhanced framework for protein structure prediction. *AIChE Journal*, 58(5), 1619–1637.

replica exchange Monte Carlo methods (Zhao *et al.*, 2010). The latest RaptorX methodology implements an integrated framework for *ab initio* and comparative structure prediction using the RaptorX server (Källberg *et al.*, 2012).

RM2TS

RM2TS uses tripeptide based backbone dihedral angle preferences derived from non-redundant experimental structures as reference to predict the tertiary structure of small proteins (DasGupta *et al.*, 2015). The allowed backbone-dihedral angle conformational space of Ramachandran maps is divided into 27 classes and has been demonstrated to be sufficient for predicting a model structure to within 5 Å RMSD, for small globular proteins with up to 100 amino acid residues. The backbone dihedral angle preferences at the tripeptide level, when coupled with predicted secondary structural elements, reduce the conventional backbone dihedral angle conformational space by a factor of ten. This reduced conformational space results in a time efficient method for structure generation with reasonably high accuracy. The tertiary structure of a protein sequence can be predicted on the basis of the backbone dihedral angles, which are derived from a precomputed look-up table, within 2–3 min on a single processor computer. Further, a higher level of accuracy can be achieved if the target sequence is complemented by an accurate secondary structure prediction. The workflow of structure prediction using RM2TS is shown in Fig. 6. A modified RM2TS methodology (with backbone dihedral angle preferences considering 11 residues window) is implemented in the BhageerathH⁺ suite.

UniCon3D

UniCon3D is a *de novo* structure prediction methodology that implements united residue conformational sampling using hierarchical probabilistic sampling. The concept of protein folding *via* sequential stabilization is utilized in this method (Bhattacharya *et al.*, 2016). The local structural preferences, in terms of backbone and side chain angle parameters are used for conformational sampling, coupled with an integrated physics-based and knowledge-based energy scoring function. Since the backbone and side chain angle parameters are considered simultaneously, the energetics of side chain solvation/desolvation are accounted for, resulting in better conformational sampling. A simulated annealing algorithm is implemented for potential energy minimization of the united-residue polypeptide conformation. Conformational sampling proceeds by stepwise construction of small fragments and their assembly into full length models. The secondary structural information utilized in the methodology considers an eight-class secondary structural element classification (3₁₀ helices, α -helices, π -helices, β -strands, β -bridges, turns, bends and coils) instead of the conventional three-class secondary structural element classification (helices, strands and coils), which brings additional accuracy to the method. Fig. 7 shows a simplified workflow of the use of UniCon3D for structure prediction using its hierarchical probabilistic sampling. The UniCon3D methodology is combined with a machine-learning-based contact-prediction method for template-based modeling in MULTICOM (Cheng *et al.*, 2012).

Accuracy Measures for Comparing Structures

The measures for similarity among protein structures have been evolving continuously over the last two decades. Several measures for quantifying the structural differences between two structures used. In this section we briefly explain some of the frequently used measures.

Fig. 6 A workflow of RM2TS protein tertiary structure prediction. Based on methodology explained in DasGupta, D., Kaushik, R., Jayaram, B., 2015. From Ramachandran maps to tertiary structures of proteins. *Journal of Physical Chemistry B*, 119(34), 11136–11145.

Fig. 7 A workflow of UniCon3D protein tertiary structure prediction where stepwise construction of small fragments and their assembly into full length models is depicted. Based on methodology explained in Bhattacharya, D., Cao, R., Cheng, J., 2016. UniCon3D: De novo protein structure prediction using united-residue conformational search via stepwise, probabilistic sampling. *Bioinformatics*, 32(18), 2791–2799.

Root Mean Square Deviation (RMSD)

RMSD is a measure of average distance between the atoms of optimally superposed protein structures (rigid body superposition) (Coutsias *et al.*, 2004). The RMSD can be calculated for only C α atoms, backbone heavy atoms (N, C, C α and O), or all atoms of the superposed structures. The C α and backbone RMSD provide a measure of similarity without considering the side chain orientations. All atom RMSD is considered as the most informative measure among all RMSDs. For exactly identical protein structures, the RMSD should be zero. RMSD between related proteins increases as the level of similarity decreases. In the context of protein structure prediction, predicted structures within 3 Å RMSD of their native structure are considered as high accuracy models, which can be used for various protein structure-based studies such as function annotation and drug design. Also, the structures within 5 Å RMSD can provide insights into the overall topology/fold of protein structures. Despite the availability of several other measures, and despite its known sensitivity to outliers, RMSD is still the most popular and widely accepted measure of structural similarity, especially among non-computational biologists.

Global Distance Test (GDT) Score

The GDT Score is the percentage of C α pairs falling within a given distance cutoff (in Å) of two optimally superposed protein structures (Zemla, 2003), typically a predicted structure and a crystallographically determined native structure. Depending upon the distance cutoff, GDT is divided into two categories, GDT-HA (GDT- High Accuracy) where usually a 2 Å cutoff is used, and GDT-TS (GDT-Template Score) where usually a 4 Å cutoff is used. The GDT score varies from 0–100 with 0 being the worst and 100 being the best. The GDT Score is used as one of the assessment parameters in CASP experiments.

Template Modeling (TM) Score

The TM Score is another measure of structural similarity between two superposed protein structures. It varies from 0 to 1, where 0 is considered as the worst and 1 as the best match (Zhang and Skolnick, 2004b). The TM Score is more sensitive to global topology than to local sub-structures.

Apart from RMSD, GDT Score and TM Score, there is a long list of parameters/methods for measuring the structural similarity which have been used in the CASP experiments. Some such scores are the Sphere Grinder (SG) Score, Global IDDT Score, CAD Score, Quality Control (QC) Score, Accuracy Self Estimate (ASE) Score, *etc.* (see Relevant Website section). It is worth mentioning that the formulae used for assessment in CASP experiments are not fixed, and new scores are introduced while old ones are dropped in every round of the CASP experiments. For instance, ASE and CAD scores were introduced in CASP12, while Mol-Probity, QC, and Contact Scores used in CASP11, were dropped. Essentially, from a modeling perspective, these measures are supposed to help identify how far the model structure is from its native conformation (Table 3).

Analysis and Assessment

Large scale genome sequencing projects have resulted in various structural genomics initiatives that seek to determine the maximum number of possible protein folds. New folds can be either explored through time consuming and expensive experimental methods or *via* computational protein-structure prediction. Sequence-based protein structure predictions using *ab initio* approaches are governed by protein folding energetics or statistical preferences, and do not explicitly need an experimental template structure. The most common strategy in *ab initio* protein structure prediction comprises sampling conformational space, steered by a force field or a scoring function and/or various sequence features, to generate a large set of candidate structures, followed by selection of native-like structures using a scoring function. Alternatively, certain methods implement clustering algorithms to reduce the number of conformations that must be scored in the latter phase of the protocol. The representative conformations of these clusters are subjected to structure refinement, and rescored for native-like structure selection. In most of the purely physics-

Fig. 8 A performance quantification of automated protein tertiary structure prediction servers which participated in the 12th round of CASP experiments. (a) For predicting low-accuracy model structures (under 7 Å RMSD), (b) For predicting medium-accuracy model structures (under 5 Å RMSD) and (c) For predicting high-accuracy model structures (under 3 Å RMSD). Data source: http://predictioncenter.org/download_area/CASP12/server_predictions/.

based methods, the conformational sampling space is explored using molecular dynamics and Monte Carlo simulations, guided by various force field parameters. At each step, the new conformation is evaluated using a scoring function, which makes these approaches computationally intensive and restricts their success to small proteins. The average length of protein sequences available in UniProtKB/Swiss-Prot (358 amino acid residues) suggests that *ab initio* methods may not be able to independently predict structures for most protein sequences. However, *ab initio* methods have been successfully integrated with comparative modeling approaches to enhance their time efficiency, and thus, their ability to predict structures of larger proteins. Table 4 lists

some *ab initio* methods (discussed above), which have been integrated into hybrid methods that achieve higher accuracy protein structure prediction without sequence length restrictions.

The performance of 43 protein structure prediction servers, participated in the 12th round of the CASP experiment (held from 2nd May to 12th July 2016), is compared *via* an in-house assessment in terms of number of structures predicted within specified RMSD ranges of the target structures: 7 Å (low-accuracy predictions), 5 Å (medium-accuracy predictions) and 3 Å (high-accuracy predictions). The assessment performed here accounts for consistency (in terms of frequencies) of accurate prediction in specified ranges of RMSD for CASP12 target proteins. The automated servers include purely *ab initio* servers, purely homology-based servers, and *ab initio*/homology-based hybrid servers. The performance comparison of different methodologies for predicting low, medium and high accuracy model structures is shown in Fig. 8. It can be observed that in all categories, servers that implement hybrid methodologies for structure prediction perform well. The different hybrid methodologies discussed here implement *ab initio* and comparative modeling components in different ways and thus perform differently on the same protein. It may happen that one server may gain while the others may have lost. Thus, in protein structure prediction regime, it is advantageous to adopt a consensus approach *via* predicting model structures from different servers, followed by a metasever approach for quality assessment.

Conclusions and Perspectives

Over the years, successful *ab initio* structure prediction strategies have metamorphosed into hybrid methodologies that can tackle proteins of any size and complexity. However, results from the recent CASP12 experiment suggest there is considerable room for further improvement. For instance, the best individual performance in the low-accuracy category (i.e., under 7 Å RMSD) was 38 out of a total of 80 domain targets (i.e. 48% success rate), which declined to 30/80 domain targets (38% success rate) for medium-accuracy predictions (i.e., under 5 Å RMSD), and to only 20/80 domain targets (25% success rate) for high accuracy predictions (i.e., under 3 Å RMSD). Considering that CASP targets are difficult to model, these success rates are of course the lower limits of the current status of the field. High accuracy predictions can be directly used for identifying ligands, modeling protein-protein interactions, functional characterization, and other structure-based drug discovery endeavours. Thus, there is a need for improved conformational sampling and scoring as well as structure refinement.

Introduction

In many scientific and technological fields there is the need to design molecules for specific goals. For instance, in Chemical Engineering many applications require to find novel materials with peculiar stress-resistance or temperature-resistance which may start from a known molecular compound, but often go towards new structures which show better fitting to the problem's specifications or constraints. In Organic Chemistry, a researcher may be interested in finding the protein responsible for a cellular process and how to accelerate the process in cases where the protein has been altered due to mutations in the genome. In Medicine contexts researchers are interested in finding new molecules or molecular approaches to cure diseases. The approach is often searching in a database of drugs to find which molecule is the best ligand for a target protein and has certain toxicity levels compatible with the treatment being designed.

Two types of molecules are usually involved in the docking process: (i) The ligand and (ii) the target molecule. Ligand, which comes from the latin term "ligare", refers to the property of the molecule to bind to another molecule. In modern chemistry, a ligand indicates a molecule that interacts with another molecule through noncovalent forces (Krumrine *et al.*, 2005). Hence, the interaction does not involve the formation of chemical bonds, which could lead to relevant chemical changes in both the ligand and the target, which is often more complex and larger in size. The final compound may be a supramolecular complex, containing multiple ligand and the target aggregates. The main forces involved in the process mainly depend on the shape of the two molecules and the influence of the solvent or the environment. In fact, the shape can be modified according to external forces (e.g., chemical bonds, solvent effect, other chemical species concentrations). These forces are usually studied using quantum mechanics. However, the direct application of quantum physics laws for such huge biological molecular systems remains limited due to computational resources limitations.

Due to the structural complexity of large molecules there is the need of smart ways to search the phase space in order to find candidate structures with minimal energy for the target-ligand molecular complex. Complications in this search can arise when dealing with metamorphic proteins, which have been observed folded in a different 3D shapes, depending on the cellular environment (Murzin, 2008). Furthermore, most computational approaches introduce significant simplifications which usually leads to a lack of generality of both the obtained model and the results.

For these reasons, the problem of finding an overall 3D structure for a ligand-protein or for a protein-protein complex is much more difficult than experimentally determining their individual 3D structures. Hence, computational techniques able to predict the interaction among proteins and between proteins and ligands are of utter importance because of the growing number of known protein structures (Vakser, 2014). Simplified computational approaches could consider the molecular shape of one or both of the chemical species as an invariant (or at least varied in a controlled way), which, albeit be a strong constraint, it helps to cut the search space for a solution with minimal energy but has to be carefully considered when adopting the resulting molecule complexes in critical applications. In fact, these results may need to be further modified to have the required features (e.g., solubility, toxicity) before being considered as viable clinical candidates.

There is a growing number of docking developers working in a wide community and producing algorithms which need assessments of methodologies. The development of more powerful docking algorithms and models can exploit the opportunity of having growing information and data resources, larger computational capabilities, and better understanding of protein interactions.

Background/Fundamentals

Structural bioinformatics is a research field which offers tools for the discovery, design and optimization of molecules (Krumrine *et al.*, 2005). However, no method exists being able to give a general solution for the many problems involved in the design of new materials.

Thousands of proteins carry out their intra- and extra-cellular functions interacting with each other (Khan *et al.*, 2013a). This observation leads to a relatively new research field called PPI, for protein-protein interaction, which models interacting protein molecules as nodes of a graph, where the arcs represent interactions between them. PPI is quite far from more classical chemical- and physical-based approaches, being a series of techniques and algorithms that map the problem of interacting molecules into the computer science problem. This allows for the efficient labeling of proteins with predicted functions inducted by similar neighbour nodes in the PPI graph.

Interactions among proteins play a fundamental role in almost every biological event such as: (i) Protein signaling, (ii) trafficking and their signal degradation (Castro *et al.*, 2005; Fuchs *et al.*, 2004), (iii) DNA repairing, replication and gene expression

(Neduva and Russell, 2006; Petsalaki and Russell, 2008). All of these cellular events require interactions between protein interfaces to function. The complexity of such iterations in the cell is huge and having complete map of them all will help in understanding how the regulatory networks work and the behaviour of the overall biological system.

Computational docking is widely used for the theoretical prediction of small molecule ligand-protein complex and is usually composed of two steps: (i) Generation of alternate shapes of a ligand molecule in order to model and simulate possible interactions with the target binding site and (ii) an energy or scoring function used to rank the various candidate structures generated at the previous step. In general, docking programs are not optimized for peptide docking, being designed and optimized to work with small molecules. Furthermore they can be deceived by the flexibility and alternative conformations of peptides which tend to rotate within the search space of the receptor site (Khan *et al.*, 2013a). For these reasons, many authors (Aloy and Russell, 2006; Gray, 2006; Russell *et al.*, 2004) recommend caution in adopting current protein-docking algorithms to detect interacting protein-ligands. Recently however, two high-throughput docking (HTD) experiments have been reported in literature, that demonstrate the ability of general docking methods in detecting protein–ligand interactions. Mosca *et al.* (2009) used docking to identify pairs of proteins interacting with each other in the *Saccharomyces cerevisiae* interactome. Furthermore, Wass *et al.* (2011) successfully distinguished between interacting native and non-interacting non-native proteins.

Computational Approaches

Optimization problems in chemistry vary from selecting the best wavelength for optimal spectroscopic concentration predictions to geometry optimization of atomic clusters and protein folding. While most optimization procedures maintain the ability to locate global optima for simple problems, few are effective against local optima convergence with regard to difficult or large scale optimization problems. Simulated annealing (SA) has shown a great tolerance to local optima convergence and it is often considered a global optimizer. The optimization algorithm has found wide use in numerous areas such as engineering, chemistry, biology, physics, and drug design. Recently, integrated approach of SA and DFT (Density Functional Theory) assured important results in developing novel drugs for diseases in different therapeutic areas (Persico *et al.*, 2017).

Car-Parrinello method represents a powerful tool of simulation in chemical engineering and biology applications. This popular approach is in fact an effective way to study phase diagrams and to identify new phases of materials, particularly at high pressure conditions. Besides, the elucidation of biological systems reactivity is extremely proficuous. It is well known that biological structures are very large and often surrounded by solvents contributing to the energy of the whole system. Taking in account the entire biomolecule would be highly time consuming. Nevertheless, a reduced model made up of atoms interested in chemical or conformational process can give a reliable insight in the system features and conversion.

Target-based drug design usually start with the 3d structure of a receptor site or the active site in a protein molecule (Krumrine *et al.*, 2005). Analog-based designs, such as pharmacophores and QSAR (quantitative structure-activity relationship), use the laws of mechanics describe the atomic level interactions and calculate an optimal molecular shape with a minimal energy. Structure-based design involves several steps: (i) 3d structure determinations, which usually involves finding it in online databases or predicting it with a prediction software tool, (ii) site representation and identification, which entails algorithms to automatically detect the binding site(s) on the external surface of the molecule (it is often the largest cavity) and its 3D shape, (iii) ligand docking, which, in case the ligand is not given, can search online databases of small molecules for ligand candidates matching the binding site; this phase could even generate novel chemical structures (de novo design) which however have to deal with the synthetic feasibility of the generated compound (iv) scoring, during which the strength of the interaction between the ligand and the binding site is evaluated.

The scoring function is a crucial element for docking. As for all the other aspects of systems containing chemical elements, a principled approach dealing with the calculation of the binding free energy between the ligand and the target protein would be computationally infeasible and extremely time consuming. The need for methods that can deal with HTD pipelines which can process a large number of (potentially large) molecules, has led to the implementation of approximate algorithmic approaches. First principle methods use a mechanics force field which represents the forces occurring between atoms and also weaker forces (e.g., Wand der Waals forces), without taking into account entropy. Nevertheless, such an approach is quite time consuming. Semiempirical approaches use a term from a linearized function to approximate absolute binding free energy, and a term from known data. Even if less time-consuming than first principle methods, these approaches are still quite time consuming. Empirically derived scoring functions are designed to be very fast in scoring ligands. Structural descriptors are selected and assigned weights calculated through regression methods using statistical models. In these approaches, the atomic details of the ligand and the binding sites are lost. Furthermore it may be difficult to find training data for particular binding sites and ligands. Knowledge-based potentials are methods where potential are not derived from experimental binding data, but from statistical analysis of atom binding frequencies measured in experimentally resolved protein-ligand complexes.

Analysis and Assessment

CAPRI (Critical Assessment of PRediction of Interactions) is an international experiment in which state of the art protein-docking methods to predict protein-protein interactions are assessed (Janin *et al.*, 2003). Many research groups participate worldwide and

submit structure predictions in a blind process for a set of protein-protein complexes based on the known structure of the component proteins. Predictions are compared to the unpublished structures of the complexes determined with X-ray crystallography at the end of the experiment. The analysis of the first editions of the competition lead to the observation that new scoring functions and for methods handling the conformation changes were needed, hence the state of the art was still not sufficient to deal with real-world molecular complexes.

In general, docking is a two phases process in which there is a search and a scoring. After the scoring has been performed, candidate complexes has to be assessed and tested to work correctly. One approach is the comparison of the RMSD (Root-Mean-Square Deviation) between the observed and the calculated complex structures. Nevertheless, RMSD can fail to detect conformational changes, not being invariant with respect to rotation and translation of the center-of-mass (Lee and Levitt, 1997). However it is widely adopted to test the scoring function results, with reported top scoring configurations being within 2 Å in 45% (Ewing *et al.*, 2001; Diller and Merz, 2001), 65% (Jones *et al.*, 1997) and 73% (Rarey *et al.*, 1996) of the cases.

Case Studies

In Søndergaard *et al.* (2009), the authors analyze the prevalence of crystal-induced artifacts and water-mediated contacts in protein-ligand complexes showing the effect they have on the performance of the scoring functions. They report that 36% of ligands in the PDBBind 2007 data set are influenced by crystal contacts and that the performance of a scoring function is affected by these.

In Khan *et al.* (2013b), the authors investigate if docking can be used to identify protein-peptide interactions with the objective of evaluating if docking could distinguish a peptide binding region from adjacent non-binding regions. They evaluated the performance of AutoDock Vina (Trott and Olson, 2010), training a bidirectional recurrent neural network using as input the peptide sequence, predicted secondary structure, Vina docking score and Pepsite score. They conclude that docking has only modest power to define the location of a peptide within a larger protein region. However, this information can be used in training machine learning methods which may allow for the identification of peptide binding regions within a protein sequence.

Biographical Sketch

Giuseppe Tradigo is a postdoc at the DIMES Department of Computer Science, Models, Electronics and Systems Engineering, University of Calabria, Italy. He has been a Research Fellow at University of Florida, Epidemiology Department, US, where he worked on a GWAS (Genome-Wide Association Study) project on the integration of complete genomic information with phenotypical data from a large patients dataset. He has also been a visiting research student at the AmMBio Laboratory, University College Dublin, where he participated to the international CASP competition with a set of servers for protein structure prediction. He obtained his PhD in Biomedical and Computer Science Engineering at University of Catanzaro, Italy. His main research interests are big data and cloud models for health and clinical applications, genomic and proteomic structure prediction, data extraction and classification from biomedical data.

Francesca Rondinelli is a young researcher. She obtained her PhD in Theoretical Chemistry at University of Calabria, Dept. of Chemistry. She has been visiting research student at KTH Royal Institute of Technology in Stockholm, Department of Chemistry. She has been a postdoc both at University of Calabria and at University of Naples, Federico II. Her research interest go from cyclodextrins, principled drug design and CO₂ activation.

Gianluca Pollastri is an Associate Professor in the School of Computer Science and a principal investigator at the Institute for Discovery and at the Institute for Bioinformatics at University College Dublin. He was awarded his M.Sc. in Telecommunication Engineering by the University of Florence, Italy, in 1999 and his PhD in Computer Science by University of California at Irvine in 2003. He works on machine learning and deep learning models for structured data, which he has applied to a cohort of problems in the bioinformatics and chemoinformatics space. He has developed some of the most accurate servers for the prediction of functional and structural features of proteins, which have processed over a million queries from all over the world and have been licensed to 75 different subjects, including pharmaceutical companies. His laboratory at UCD has been funded by Science Foundation Ireland, the Health Research Board, the Irish Research Council, Microsoft, UCD, the King Abdulaziz City for Science and Technology (Saudi Arabia) and Nvidia.

Introduction

Network Analysis (hereafter, NA) has been a multidisciplinary research field from its origin. Relationship represents the key concept in a network. Indeed, relationships, and not participants, give the main contribution to model a network (Hanneman and Riddle, 2005; Tsvetovat and Kouznetsov, 2011).

NA allows the identification of relationship patterns existing in a network. Moreover, it allows the detection, and the next investigation, of the information (and/or other resource) flow among participants. Finally, it focuses on interactions among participants, which differentiates it from other kinds of analysis that mainly investigate the features of a single participant.

Network analysis-based approaches allow interactions in a group to be mapped, as well as the connectivity of a network to be visualized and investigated. Furthermore, they make it possible to quantify the processes taking place among network participants (Knoke and Yang, 2008; Scott, 2012; Wasserman and Galaskiewicz, 1994).

Two research fields where the employment of NA is rapidly increasing are bioinformatics and biomedicine. Think, for instance, of Public Health (Luke and Harris, 2007; Berkman and Glass, 2000; House *et al.*, 1988). According to Luke and Harris (2007), it is possible to find three main typologies of network in this sector, namely: (i) transmission networks, (ii) social networks, and (iii) organizational networks. Transmission networks are particularly relevant and, therefore, largely investigated. They allow the analysis of the diffusion of both diseases (Friedman and Aral, 2001; Friedman *et al.*, 1997; Jolly *et al.*, 2001; Aral, 1999; Valente and Fosados, 2006) and medical information (Valente and Fosados, 2006; Katz and Lazarsfeld, 1955; Valente, 1995; Guardiola *et al.*, 2002; Valente and Davis, 1999). Two very relevant application contexts for transmission networks are social epidemiology (Berkman *et al.*, 2014; Haustein *et al.*, 2014) and information diffusion on social networks (Eysenbach, 2008; Scanfeld *et al.*, 2010; Hawn, 2009; Laranjo and Arguel, 2014; Xu *et al.*, 2015). Social networks investigate how social structures and relationships influence both public health and people behavior (Kessler *et al.*, 1985; Berkman, 1984; Cassel, 1976; Kaplan *et al.*, 1977; Lin *et al.*, 1999). Organizational networks represent the most recent research sector; in this case, researchers evaluate the impact of associations and/or agencies on public health (Leischow and Milstein, 2006; Borgatti and Foster, 2003; Becker *et al.*, 1998; Mueller *et al.*, 2004; Kapucu, 2005).

In bioinformatics, an important investigation regards the usage of "information-based" tools to analyze medical problems. In this case, two very important research areas are molecular analysis (Wu *et al.*, 2009; Cusick *et al.*, 2009; Gandhi *et al.*, 2006; Han, 2008; Sevimoglu and Arga, 2014) and brain analysis (Rubinov and Sporns, 2010; Greicius *et al.*, 2003; Achard *et al.*, 2006; Supekar *et al.*, 2008; Zalesky *et al.*, 2010). Another relevant investigation concerns the definition of software packages and analytic tools allowing extensive studies on large datasets (Huang *et al.*, 2009; Librado and Rozas, 2009; Zhang and Horvath, 2005; Langfelder and Horvath, 2008; Kears *et al.*, 2012; Chen *et al.*, 2009).

In this analysis, two of the most used indexes are: (i) centrality indicators (adopted, for instance, in Yoon *et al.* (2006) and Junker (2006)), and (ii) connection indicators (employed, for instance, in Girvan and Newman (2002), Estrada (2010), Wu *et al.* (2011)). An overview on the usage of these indicators can be found in Ghasemi *et al.* (2014). For instance, Closeness Centrality is used in Hahn and Kern (2005) to study the evolution of protein-protein networks. In Ozgur *et al.* (2008), the authors use eigenvector centrality to predict good candidate disease-related genes. In del Rio *et al.* (2009), the authors adopt 16 different centrality measures to analyze 18 metabolic networks. Finally, in Hsu *et al.* (2008), the authors employ both centrality and cohesion indexes for understanding how miRNAs influence the protein interaction network.

This article is organized as follows. In Section "Network Representation", we describe how networks can be represented. In Section "Index Description", we illustrate the main indexes employed in network analysis. Finally, in Section "Closing Remarks", we draw our conclusions.

Network Representation

A network $\mathcal{N} = \langle V, E \rangle$ consists of a set V of nodes and a set E of edges. Each edge $e_{ij} = (v_i, v_j)$ connects the nodes v_i and v_j . Edges can be either directed (when they can be traversed only in one direction) or undirected (when they can be traversed in both directions). Furthermore, networks can be weighted or unweighted. If a network is weighted, it can be represented as (v_i, v_j, w_{ij}) , where w_{ij} denotes the weight of the corresponding edge. On the basis of the reference context, this weight could represent strength, distance, similarity, etc.

Example 2.1: Consider the networks in Fig. 1. The one on the left is undirected and unweighted, whereas the one on the right is directed and weighted. For instance, the edge A–C in the network on the right indicates that there is a link from A to C and that the weight of this link is 34. □

Fig. 1 An example of undirected and unweighted network (on the left), and an example of directed and weighted network (on the right).

	A	B	C	D	E	F
A	0	1	1	1	0	1
B	1	0	1	0	0	0
C	1	1	0	1	0	0
D	1	0	1	0	1	0
E	0	0	0	1	0	1
F	1	0	0	0	1	0

	A	B	C	D	E	F
A	0	0	34	21	0	0
B	1	0	1	0	0	0
C	0	2	0	3	0	0
D	0	0	0	0	5	0
E	0	0	0	0	0	8
F	13	0	0	0	0	0

Fig. 2 The Adjacency Matrixes corresponding to the networks of Fig. 1.

Table 1 The edge lists corresponding to the networks of Fig. 1

Undirected and unweighted network	Directed and weighted network
(A,B), (A,C), (A,D), (A,E), (B,C), (C,D), (D,E), (E,F)	(A,C, 34), (A,D,21), (B,A,1), (C,B,2), (C,D,3), (D,E,5), (E,F,8), (F,A,13)

Table 2 The adjacency lists corresponding to the networks of Fig. 1

Undirected and unweighted network	Directed and weighted network
A – {B, C, D, E}	A – {(C,34), (D,21)}
B – {C}	B – {(A,1)}
C – {D}	C – {(B,2), (D,3)}
D – {E}	D – {(E,5)}
E – {F}	E – {(F,8)}
F – {}	F – {(A,13)}

The basic way to represent a network $\mathcal{N}$ employs the so called adjacency matrix $\mathcal{A}$. This is a $|V| \times |V|$ matrix. Each row and each column correspond to a node. If $\mathcal{N}$ is unweighted, the generic element $\mathcal{A}[i, j]$ is set to 1 if there exists an edge from v_i to v_j ; otherwise, it is set to 0. By contrast, if $\mathcal{N}$ is weighted, $\mathcal{A}[i, j]$ is set to the weight of the edge from v_i to v_j . Finally, if $\mathcal{N}$ is undirected, the corresponding adjacency matrix is a lower triangular one. The adjacency matrix is very easy to be understood; however, in real cases, it is very sparse (i.e., most of its elements are set equal to 0) and, therefore, it wastes a lot of space.

To reduce the waste of space, $\mathcal{N}$ can be represented as an edge list $\mathcal{L}$. In this case, if $\mathcal{N}$ is unweighted, $\mathcal{L}$ consists of a list of pairs, each representing an edge with its starting and ending nodes. By contrast, if $\mathcal{N}$ is weighted, $\mathcal{L}$ consists of a list of triplets, each representing an edge with the corresponding starting node, ending node and weight. Clearly, edge list is more compact, but less clear, than adjacency matrix.

A further reduction of the space needed to represent $\mathcal{N}$ is obtained by adopting an adjacency list $\mathcal{L}^*$. If $\mathcal{N}$ is unweighted, $\mathcal{L}^*$ consists of a list of pairs $\langle v_i, \mathcal{L}'_i \rangle$, where v_i is a node of $\mathcal{N}$ and $\mathcal{L}'_i$ is the list of the nodes reachable from it. If $\mathcal{N}$ is weighted, $\mathcal{L}^*$ consists of a list of pairs $\langle v_i, \mathcal{L}''_i \rangle$, where v_i is a node of $\mathcal{N}$ and $\mathcal{L}''_i$ is, in turn, a list of pairs $\langle v_j, w_{ij} \rangle$, such that v_j is reachable from v_i and w_{ij} is the weight of the corresponding edge. Clearly, among the three structures presented above, the adjacency list is the most compact, but also the least clear one.

Example 2.2: (...cnt'd)

Consider the networks shown in Fig. 1. The corresponding adjacency matrixes are reported in Fig. 2. The associated edge lists are shown in Table 1. Finally, the corresponding adjacency lists are illustrated in Table 2. $\square$

Index Description

Basic Indexes

The most basic, yet extremely important, index for a network $\mathcal{N}$ is its *size*. It consists of the number of its nodes.

Given a node v_i of $\mathcal{N}$, if this last is *undirected*, the number of edges connecting v_i to the other nodes of $\mathcal{N}$ represents the *degree* of v_i . If $\mathcal{N}$ is *directed*, the number of edges incoming to (resp., outgoing from) v_i represents the *indegree* (resp., the *outdegree*) of v_i .

If $\mathcal{N}$ is *undirected*, it is possible to consider the *mean degree*, i.e., the ratio of the sum of the degrees of its nodes to the number of nodes. If $\mathcal{N}$ is *directed*, it is possible to define the *mean indegree* and the *mean outdegree* of $\mathcal{N}$ in an analogous fashion.

If $\mathcal{N}$ is unweighted, its *density* is simply the ratio of its edges to the number of all its possible edges. Recall that the number of all possible edges of $\mathcal{N}$ is $\frac{|V| \cdot (|V| - 1)}{2}$, if $\mathcal{N}$ is undirected, whereas it is $|V| \cdot (|V| - 1)$, if $\mathcal{N}$ is directed. If $\mathcal{N}$ is weighted, its *density* can be defined as the ratio of the sum of the weights of the existing edges to the number of all its possible edges.

Example 3.1: (...cnt'd)

Consider the undirected network of Fig. 1. Its size is 6. The degree of the node A of this network is 4. The mean degree of the network is 2.6, whereas its density is 0.53.

Consider, now, the directed network of the same figure. Its size is 6. The indegree of the node D is 2, whereas its outdegree is 1. The mean indegree (resp., outdegree) of the network is 1.33 (resp., 1.33). Finally, its density is 2.90. □

Given a network $\mathcal{N}$, a *walk* of $\mathcal{N}$ consists of an alternating sequence of nodes and edges that begins and ends with a node. If the starting and the ending nodes of a walk are different, it is said *open*; otherwise, it is said *close*. If no node is crossed twice, a walk is said *simple*.

Given a network $\mathcal{N}$, a *path* is an open simple walk. A *cycle* is a closed simple walk. A *trail* is a walk that includes each edge no more than once. A *tour* is a closed walk comprising each edge of $\mathcal{N}$ at least once.

If $\mathcal{N}$ is unweighted, the *length* of a walk of $\mathcal{N}$ consists of the number of its edges. If $\mathcal{N}$ is weighted, the length of a walk of $\mathcal{N}$ is the sum of the weights of its edges. Given two nodes v_i and v_j of $\mathcal{N}$, their *geodesic distance* is the length of the shortest path from v_i to v_j . Given a node v_i , the *eccentricity* of v_i is the maximum geodesic distance between v_i and any other node of $\mathcal{N}$. Finally, the *radius* of $\mathcal{N}$ is the minimum eccentricity over all its nodes, whereas, if $\mathcal{N}$ is connected, the *diameter* of $\mathcal{N}$ is the maximum eccentricity over all its nodes.

Example 3.2: (...cnt'd)

Consider the directed weighted network of Fig. 1. An example of walk is the one linking nodes A–D–E–F–A–C. This is an open walk. Vice versa, an example of close walk is B–A–C–B. Since no node is crossed twice, this walk is simple.

The walk A–C–D is an example of path, whereas the walk A–C–D–E–F–A is an example of cycle. The walk A–C–D–E is an example of trail. Finally, the walk A–C–B–A–C–D–E–F–A–D–E–F–A is an example of tour. The length of the walk A–D–E–F is 34. Consider, now, nodes C and A. Their shortest path is C–B–A. The distance of this shortest path is 3 and represents the geodesic distance from C to A. The eccentricity of the node C is 16. Finally, the diameter of this network is 62. □

Centrality Indexes

Centrality indexes aim at measuring power, influence, or other similar features, for the nodes of a network. In real life, there is an agreement on the fact that power and influence are strictly related to relationships. By contrast, there is much less agreement about what power and influence mean. Therefore, several centrality indexes have been proposed to capture the different meanings associated with the term “power”.

Degree centrality

In a network, nodes having more edges to other nodes may have an advantage. In fact, they may have alternative ways to communicate, and hence are less dependent on other nodes. Furthermore, they may have access to more resources of the network as a whole. Finally, because they have many edges, they are often third-parties in exchanges among others, and can benefit from this brokerage. As a consequence of all these observations, a very simple, but often very effective, centrality index is node degree. The corresponding form of centrality is called *degree centrality*.

In an undirected network, the degree centrality of a node is exactly the number of its edges. In a directed network, instead, it is important to distinguish centrality based on indegree from centrality based on outdegree. If a node has a high indegree, then many nodes direct edges to it; as a consequence, a high indegree implies *prominence* or *prestige*. If a node has a high outdegree, then it is able to exchange with many other nodes; as a consequence, a high outdegree implies *influence*.

Generally, in a network, degree centrality follows a power-law distribution. This implies that there are few nodes with a high degree centrality and many nodes with a low degree centrality.

Closeness centrality

A weak point of degree centrality is that it considers only the immediate edges of a node or the edges of the neighbors of a node, rather than indirect edges to all the other nodes. Actually, a node might be linked to a high number of other nodes, but these last

ones might be rather disconnected from the network as a whole. If this happens, the node could be quite central, but only in a local neighborhood.

Closeness centrality emphasizes the distance (or, better, the closeness) of a node to all the other nodes in the network. Depending on the meaning we want to assign to the term “close”, a number of slightly different closeness measures can be defined.

In order to compute the closeness centrality of the nodes of a network, first the length of the shortest path between every pair of nodes must be computed. Then, for each node: (i) the average distance to all the other nodes is computed; (ii) this distance is divided by the maximum distance; (iii) the obtained value is subtracted from 1. The result is a number between 0 and 1; the higher this number, the higher the closeness and, consequently, the lower the distance.

As for the distribution of the values of closeness centrality in a network, generally few nodes form a long tail on the right but all the other nodes form a bell curve residing at the low end of the spectrum.

Betweenness centrality

Betweenness centrality starts from the assumption that a node v_i of a network $\mathcal{N}$ can gain power if it presides over a communication bottleneck. The more nodes of $\mathcal{N}$ depend on v_i to make connections with other nodes, the more power v_i has. On the other side, if two nodes are connected by more than one shortest path and v_i is not on all of them, it loses some power. The betweenness centrality of v_i considers exactly the proportion of times v_i is in the shortest path between other nodes; the higher this proportion the higher betweenness centrality.

Betweenness centrality also allows the identification of boundary spanners, i.e., nodes acting as bridges between two or more subnetworks that, otherwise, would not be able to communicate to each other. Finally, betweenness centrality also measures the “stress” which v_i must undergo during the activities of $\mathcal{N}$.

Betweenness centrality can be measured as follows: first, for each pair of nodes of $\mathcal{N}$, the shortest path is computed. Then, for each node v_i of $\mathcal{N}$, the number of the shortest paths, which v_i is involved on, is computed. Finally, if necessary, the obtained results can be normalized to the range [0,1].

Eigenvector centrality

Eigenvector centrality starts by the assumption that, in order to evaluate the centrality of a node v_i in a network $\mathcal{N}$, instead of simply adding the number of edges to compute degree, one should weight each of the edges by the degree of the node at the other end of the link (i.e., well connected nodes are worth more than badly connected ones). In this case, v_i is central if it is connected to other nodes that, in turn, are central. A node with a high eigenvector centrality is connected to many nodes that are themselves connected to many nodes.

Eigenvector centrality allows the identification of the so called “gray cardinals”, i.e., nodes representing, for instance, advisors or decision makers operating secretly and unofficially. For instance, Don Corleone was a “gray cardinal” because he had an immense power, since he surrounded himself with sons and his trusted “capos”, who handled his affairs. By knowing well connected people, “gray cardinals” can use these relationships to reach their objectives while staying largely in the shadow.

The eigenvector centrality of v_i can be computed as follows: (i) a centrality score of 1 is assigned to all nodes; (ii) the score of each node is computed as a weighted sum of the centralities of all the nodes of its neighborhood; (iii) obtained scores are normalized by dividing them by the largest score; (iv) steps (ii) and (iii) are repeated until the node scores stop changing.

PageRank

PageRank overcomes the idea of centrality. In fact, instead of outgoing edges, PageRank centrality is determined through incoming edges. PageRank was originally developed for indexing web pages. In fact, it is the algorithm used by Google for this purpose. However, it can be applied to all directed networks.

PageRank follows the same ideas of eigenvector centrality, i.e., the PageRank of v_i depends on the number of edges incoming to it, weighted by the PageRank of the nodes at the other end of the edge.

Analogously to what happens for the computation of the eigenvector centrality, the computation of PageRank is iterative. However, differently from Eigenvector Centrality, PageRank computation is local in nature, because only immediate neighbors are taken into consideration; however, its iterative nature allows global influence to propagate through the network, although much more attenuated than eigenvector centrality. As a consequence of its local nature, the computation of PageRank scales much better to very large networks. Furthermore, at any time, it returns a result, but if more iterations are performed, the quality of results improves a lot.

Cohesion Indexes

One of the main issues in NA is the identification of cohesive subgroups of actors within a network. Cohesive subgroups are subsets of actors linked by strong, direct, intense, frequent and/or positive relationships. Cohesion indexes aim at supporting the identification of cohesive subnetworks in a network.

To introduce cohesion indexes, we must start with the concept of subnetwork. A *subnetwork* consists of a subset of nodes of a network and of all the edges linking them.

An *ego-network* is a subnetwork consisting of a set of nodes, called “alters”, connected to a focal node, called “ego”, along with the relationships between the ego and the alters and any relationships among the alters. These networks are important because the analysis of their structure provides information useful to understand and predict the behavior of ego.

Triads

A *triad* is a triple of nodes and of the possible edges existing among them.

With *undirected networks*, there are four possible kinds of relationship among three nodes (see Fig. 3), i.e., no edges, one edge, two edges or three edges. Triad census aims at determining the distribution of these four kinds of relationship across all the possible triads. It can give a good approximation of how much a population is characterized by “isolation”, “couples only”, “structural holes” or “closed triads”. In this context, “structural holes” represent a very interesting concept. Given three nodes v_i , v_j and v_k , there exists a structural hole if v_i is connected to v_j , v_j is connected to v_k but v_i is not connected to v_k . Structural holes have important implications in a network; in fact, they are nodes capable of using and handling asymmetric information; furthermore, they can also bridge two communities. The *ratio between structural holes and closed triads* is a very important index, because, if it is high, then the corresponding network tends to be hierarchic, whereas, if it is low, then the corresponding network tends to be egalitarian.

With *directed network*, there are 16 possible kinds of relationship among three nodes (see Fig. 4), including those exhibiting hierarchy, equality, the formation of exclusive groups or clusters. A very important scenario is that of *transitive triads* (i.e., relationships where, if there are edges from v_i to v_j and from v_j to v_k , then there is also an edge from v_i to v_k). Such triads represent the “equilibrium” toward which triadic relationships tend.

Cliques

In its most general definition, a clique is a subnetwork of a network $\mathcal{N}$ in which its nodes are more closely and intensely linked to each other than they are the other nodes of $\mathcal{N}$. In its most formal and rigorous form, a *clique* is defined as a maximal totally connected subnetwork of a given network. The smallest clique is the dyad, consisting of two nodes linked by an edge. Dyads can be extended to become more and more inclusive in such a way as to form strong or closely connected regions in graphs. A clique consists of several overlapping closed triads and, as such, it inherits many of the properties of closed triads.

This rigorous definition of a clique may be too strong in several situations. Indeed, in some cases, at least some members are not so strongly connected. To capture this cases, the definition of clique can be relaxed.

One way to do so is to define a node as a member of a clique if it is connected to each node of the clique at a distance greater than 1. In this case, the path distance 2 is used. This definition of clique is called *N-clique*, where N stands for the maximum length of the allowed path. The definition of N-clique presents some weaknesses. For instance, it tends to return long and stringy N-cliques. Furthermore, N-cliques have properties undesirable for many purposes. For instance, some nodes of N-cliques could be connected by nodes that are not, themselves, members of the N-clique. To overcome this last problem, it is possible to require that the path distance between any two nodes of an N-clique satisfies a further condition, which forces all links among members of an N-clique to occur by way of other members of the N-clique. The structure thus obtained is called *N-clan*.

Fig. 3 The possible kinds of relationship involving a triad in an undirected network.

Fig. 4 The possible kinds of relationship involving a triad in a directed network.

An alternative way of relaxing the rigorous definition of clique consists of allowing nodes to be members of a clique even if they have edges to all but k other members. In other words, a node is a member of a clique of size N if it has edges to at least $N - k$ nodes of that clique. This relaxation leads to the definition of k -plex. While the N-clique approach often leads to large and stringy groupings, the k -plex approach often returns large numbers of smaller groupings. Depending on the goals of the analysis, both N-clique and k -plex could provide useful information about the sub-structure of groups.

A k -core is a maximal group of nodes all of whom connected to at least k other nodes of the group. The k -core approach is more relaxed than the k -plex one; indeed, it allows a node to join the group if it is connected to k other nodes, regardless of how many other nodes it may not be connected to. By varying the value of k different group structures can emerge. K-cores usually are more inclusive than k -plexes.

If a network is weighted, it is possible to introduce a last concept, i.e., the concept of F -groups. F -groups return the maximal groups formed by “strongly transitive” and “weakly transitive” triads. A strongly transitive triad exists if there is an edge (v_i, v_j, w_{ij}) , an edge (v_j, v_k, w_{jk}) and an edge (v_i, v_k, w_{ik}) and $w_{ij} = w_{jk} = w_{ik}$. A weakly transitive triad exists if w_{ij} and w_{jk} are both higher than w_{ik} , but this last is greater than some cut-off value.

Components

Components of a network are subnetworks that are connected within, but disconnected between networks. Interesting components are those dividing the network into separate parts such that each part has several nodes connected to one another (regardless of how much they are closely connected).

For directed networks, it is possible to define two different kinds of component. A weak component is a set of nodes that are connected, regardless of the direction of edges. A strong component also considers the direction of edges, when it verifies node connection.

Rather as the strict definition of clique may be too strong to capture the concept of maximal group, the notion of component may be too strong to capture all the meaningful weak points, holes and locally dense sub-parts of a larger network. Therefore, also for components, some more flexible definitions have been proposed. Due to space limitations, we do not illustrate these definitions in detail.

Other Indexes

In this section, we present some other concepts about NA that can be very useful in Bioinformatics and Computational Biology. The first concept regards the diffusion in a network. Several past studies show that the diffusion rate in a network is initially linear. However, if a *critical mass* is reached, this rate becomes exponential until the network is saturated. The same investigations show that the critical mass is reached when about 7% of nodes are reached by the diffusion process. From an economic point of view, in a diffusion process, critical mass is reached when benefits start outweighing costs. If benefits do not balance costs, the critical mass is not obtained, and the diffusion process itself will fail eventually.

If diffusion regards information, there are several indexes that can help to foresee if a node v_i will contribute to the diffusion process. These indexes are: (i) *relevance* (does v_i care at all?); (ii) *saliency* (does v_i care right now?); (iii) *resonance* (does information content mesh with what the actor associated with v_i believes in?); (iv) *severity* (how good or bad is information content?); (v) *immediacy* (does information require an immediate action?); (vi) *certainty* (does information cause pain or pleasure?); (vii) *source* (which did information come from and does v_i trust this source?); (viii) *entertainment value* (is information funny?).

To understand the behavior of actors in a network, a key concept is *homophily*. It states that two actors, who share some properties, will more likely form links than two actors, who do not. Other ways to express the same concept state that: (i) two actors being very close to a third one in a network often tend to link to each other; (ii) two actors sharing attributes are likely to be at closer distance to one another in networks.

In real networks, homophily is a major force, which, if left alone, would lead communities to become excessively uniform. To avoid this risk, two important elements act in real life, i.e., curiosity and weak ties. In particular, it was shown that weak ties are much more powerful than strong ties to stimulate innovation in the behavior of an actor or of a whole network.

A final important index to consider in this section is the so called *Dunbar number*. This index was determined by Robin Dunbar, who showed that, in real life, the average number of contacts that a person can really handle is 150 and that this number is limited by the size of our prefrontal cortex, as well as by human ability to reason about other people and relationships.

Closing Remarks

In this article, we have provided a presentation of several graph indexes and descriptors. We have seen that network analysis is largely employed in bioinformatics and biomedicine. Then, we have illustrated the most common network representations proposed in the past. Finally, we have presented a large variety of both basic and advanced indexes and descriptors. We think that the usage of graph-based indexes and descriptors in bioinformatics did not come to an end. On the contrary, in the future, the availability of large amounts of data in these contexts, along with the development of more and more powerful hardware, will lead to more and more complex and effective approaches for facing the new challenges that will appear in these sectors.

Algorithms for Graph and Network Analysis: Traversing/Searching/Sampling Graphs

Paolo Lo Giudice and Domenico Ursino, University “Mediterranea” of Reggio Calabria, Reggio Calabria, Italy

© 2019 Elsevier Inc. All rights reserved.

Introduction

Differently from other data analytics tasks, Network Analysis (NA) (Carrington *et al.*, 2005; Knoke and Yang, 2008; Wasserman and Galaskiewicz, 1994; Scott, 2012) focuses on *relationships* existing between actors, instead of on actors.

In Network Analysis, one of the most common issues regards the computational effort necessary for performing investigations. One of the most usual ways to face this issue consists in the adoption of sampling. Indeed, sampling approaches allow the extraction of knowledge about a network by investigating only a part of the network itself.

Clearly, the way the sample is chosen becomes crucial for extracting knowledge without errors or, at least, for minimizing the magnitude of errors. The problem of sampling from large graphs is discussed in Leskovec and Faloutsos (2006). Here, the authors investigate: (i) which sampling approaches must be used; (ii) how much the sampled graph can be reduced w.r.t. the original graph; (iii) how the measurements of a sample can be scaled up to get estimates for the corresponding (generally much larger) graph. The problem to obtain realistic samples with an as small as possible dimension is also described in Krishnamurthy *et al.* (2005). Here, the authors show that some of the analyzed methods can maintain the key properties of the original graph, even if the sample dimension is about 30% smaller than the original graph.

Sampling has been studied very much in the literature. For instance, in Gilbert and Levchenko (2004), the authors propose an approach that, given a communication network, determines the most important nodes and, then, links them each other. Instead, the authors of Rafei and Curial (2012) propose a technique, based on both sampling and the randomized notion of *focus*, to allow the visualization of very large networks. An analysis of the statistical properties of a sampled network can be found in Lee *et al.* (2006). In Ahn *et al.* (2007), the authors use the social network Cyworld to analyze the main features of the snowball sampling approach.

Other approaches, such as Chau *et al.* (2007), Gjoka *et al.* (2010), Kurant *et al.* (2010), Ye *et al.* (2010), focus mainly on sampling cost. Specifically, Ye *et al.* (2010) analyzes how much rapidly a crawler can reach nodes and links; Chau *et al.* (2007) proposes a framework of parallel crawlers based on Breadth First Search (BFS); Kurant *et al.* (2010) investigates the impact of different sampling techniques on the computation of the average node degree of a network; Gjoka *et al.*, (2010) studies several crawling strategies and determines the sampling quality guaranteed by them and the computation effort they require. Finally, in Buccafurri *et al.* (2014a,b), the authors describe how the crawling problem and its solutions change when passing from a social networking to a social internetworking scenario (i.e., in a scenario where several social networks interact each other through *bridge* nodes).

In bioinformatics and biomedicine, sampling of complex networks is a new and little investigated task. One of the main issues faced in these two contexts is the rapid growth of the scientific knowledge presented in the literature. Sampling is mainly used to classify such a knowledge. As a consequence, currently it is a supporting task for performing other activities, and is employed only rarely as the core task of an approach to facing issues in this context. For instance, in Coulet *et al.* (2010), Jin *et al.* (2008), Plaza *et al.* (2011), the authors present some approaches that employ sampling on the existing literature to create: (i) semantic maps based on relationships (Coulet *et al.*, 2010); (ii) summarizations (Plaza *et al.*, 2011); (iii) multi-label classifications (Jin *et al.*, 2008).

Sampling is also used to face a specific, yet extremely interesting, research problem, i.e., the search of motifs in a network. For instance, the authors of Kashtan *et al.* (2004) propose a new algorithm allowing the estimation of the subgraph concentration at runtime; furthermore, in Boomsma *et al.* (2008), the authors employ sampling to generate a probabilistic model of local protein structure; finally, in Alon *et al.* (2008), Wong *et al.* (2011), sampling is used to search motifs in biological networks.

In biomedical research, the most employed sampling approach is undoubtedly Random Walk (RW) and its variants. For instance, RW is adopted in Liu *et al.* (2016), Navlakha and Kingsford (2010) to evaluate the relationships between proteins, genes and diseases. In Leong and Morgenthaler (1995), the authors employ RW to investigate and plot DNA sequences. Finally, in Freschi (2007), Liu *et al.* (2013), Macropol *et al.* (2009), RW is used to discover functional models and to infer the pathway activity. In these last cases, RW allows users to capture the information embedded in structure and to represent it in the resulting graph.

This article aims at providing an exhaustive overview of the existing algorithms for traversing, searching and sampling networks. It is organized as follows. In Section Fundamentals, we illustrate some preliminary concepts and introduce the formalism adopted throughout this article. In Section Sampling Approaches, first we propose three taxonomies for sampling approaches and, then, we provide a brief description of each approach. In Section Analysis and Assessment, we present a comparison of sampling approaches based on property preservation and network property estimation. Finally, in Section Closing Remarks, we draw our conclusions and have a look at future possible developments of this research issue.

Fundamentals

A network $\mathcal{N} = \langle V, E \rangle$ consists of a set V of nodes and a set E of edges. We use $\mathcal{N}$ and m to denote $|V|$ and $|E|$. Each edge $e_{ij} = (v_i, v_j)$ connects the nodes v_i and v_j . Edges can be either directed (when they can be traversed only in one direction) or undirected (when they can be traversed in both directions). Furthermore, networks can be weighted or unweighted. If a network is weighted, the edge can be represented as (v_i, v_j, w_{ij}) , where w_{ij} denotes the weight of the edges. On the basis of the reference context, this weight could represent strength, distance, similarity, etc.

Let v_i be a node of V . The set of edges incident to v_i is defined as $\iota(v_i) = \{(v_j, v_i, w_{ji}) | (v_j, v_i, w_{ji}) \in E\}$. The neighborhood $\nu(v_i)$ is defined as $\nu(v_i) = \{v_j | (v_i, v_j, w_{ij}) \in E\}$.

A sampled network $\mathcal{N}_s = \langle V_s, E_s \rangle$ consists of a set $V_s \subseteq V$ of nodes and a set $E_s \subseteq E$ of edges such that $E_s \subseteq \{(v_i, v_j, w_{ij}) | v_i \in V_s, v_j \in V_s\}$. This last condition ensures that the sampled elements form a valid graph. We use the symbols $\mathcal{N}_s$ and m_s to denote $|V_s|$ and $|E_s|$, respectively. Clearly, $\mathcal{N}_s \leq \mathcal{N}$ and $m_s \leq m$. Each sampling activity has a cost and, often, a maximum budget B can be assigned to it.

Sampling Approaches

Taxonomies of Sampling Approaches

There exist several taxonomies of sampling approaches. A first classification considers the sampling objective. In this case, we can distinguish approaches that: (i) get a representative subset of nodes; (ii) preserve certain properties of the original network; (iii) generate a random network. As for this article, we will give more importance to the second type, i.e., property preservation.

A second taxonomy concerns the type of networks. In this case, we have: (i) Erdos-Renyi Network (ERN), also known as Random Graph, Exponential Random Graph, Poisson Random Graph, etc.; (ii) Power-Law Network (PLN), also called Scale-Free Network; (iii) Small-World Network (SMN); (iv) Fixed Degree Distribution Random Graph (FDDRG), also called "Configuration Model".

A third taxonomy is based on the adopted sampling techniques. In this case, we can consider:

- Node Sampling (NS).
- Edge Sampling (ES).
- Node Sampling with Neighborhood (NSN).
- Edge Sampling with Contraction (ESC).
- Node Sampling with Contraction (NSC).
- Traversal Based Sampling (TBS). This last is actually a family of techniques. In this case, the sampler starts with a set of initial nodes (and/or edges) and expands the sample on the basis of current observations. In this family, we can recognize:
 - Breadth First Search (BFS);
 - Depth First Sampling (DFS);
 - Random First Sampling (RFS);
 - Snowball Sampling (SBS);
 - Random Walk (RW);
 - Metropolis-Hastings Random Walk (MHRW);
 - Random Walk with Escaping (RWE);
 - Multiple Independent Random Walkers (MIRW);
 - Multi-Dimensional Random Walk (MDRW);
 - Forest Fire Sampling (FFS);
 - Respondent Driven Sampling (RDS) or Re-Weighted Random Walk (RWRW).

In the following, we use this last taxonomy and we give an overview to all the approaches mentioned above for it.

Description of Sampling Approaches

Node Sampling (NS)

This approach first selects V_s directly, i.e., uniformly or according to some distribution of V , determined on the basis of information about nodes already known. Then, it selects the edges of E_s in such a way that $E_s = \{(v_i, v_j, w_{ij}) | (v_i, v_j, w_{ij}) \in E, v_i \in V_s, v_j \in V_s\}$.

Edge Sampling (ES)

This approach first selects $E_s \subseteq E$ somehow. Then, it selects V_s as $V_s = \{v_i, v_j | (v_i, v_j, w_{ij}) \in E_s\}$. Alternatively, it can set $V_s = V$. In this last case, the edge sampling task reduces to a network sparsification task. As a matter of facts, network sparsification is a more general task than network sampling. Therefore, the latter can be considered as a specific case of the former.

Node Sampling with Neighborhood (NSN)

This approach first selects a set $\bar{V} \subseteq V$ directly, on the basis of available resources, without considering topology information. Then, it determines E_s as $E_s = \cup_{v_i \in \bar{V}} t(v_i)$ and $V_s = \{v_i, v_j | (v_i, v_j) \in E_s\}$. Finally, it returns $\mathcal{N}_s = \langle V_s, E_s \rangle$ as the sampled network.

Edge Sampling with Contraction (ESC)

This is an iterative process. At each step, it samples one edge $(v_i, v_j, w_{ij}) \in E$ and performs the following tasks: (i) it substitutes nodes v_i and v_j with only one node v_{ij} representing both of them; (ii) it substitutes each edge involving v_i or v_j with an edge involving v_{ij} ; (iii) it substitutes all the possible edges involving v_{ij} and the same node v_k with a unique edge involving the same nodes, whose weight is suitably determined from the weights of the merged edges, depending on the application context.

Node Sampling with Contraction (NSC)

This is an iterative process. At stage l , it samples one node v^l and contracts v^l and the nodes of $v(v^l)$ into one node. In carrying out this task, it suitably removes or modifies the corresponding edges. It is possible to show that NSC is a more constrained version of ESC.

Breadth First Search/Sampling (BFS), Depth First Search/Sampling (DFS), Random First Search/Sampling (RFS)

The Breadth First Sampling approach uses a support list L of nodes. Initially, it selects a starting node v^0 and sets L to $\{v^0\}$, V_s to $\{v^0\}$ and E_s to $\emptyset$. Then, it repeats the following tasks until the available budget B is exhausted: (i) it takes the first element v^l from L ; (ii) for each $v_j \in v(v^l)$ such that $v_j \notin V_s$ and $v_j \notin L$, it adds v_j to L ; v^l is called the “father” of v_j and is indicated as $f(v_j)$; (iii) it adds v^l to V_s ; (iv) it adds the edge (v^l, v_j) to E_s ; (v) it subtracts the cost of the current iteration from B .

DFS and RFS differ from BFS only in step (i) above. In fact, in DFS, the last element is selected from L , whereas, in RFS, a random element is chosen.

Snowball Sampling (SBS)

Snowball Sampling, or Network Sampling or Chain Referral Sampling, is often used in sociology when it is necessary to perform an investigation on a hidden population (e.g., alcoholists).

It starts from an initial set V^0 of nodes, which can be obtained randomly or based on the side knowledge of the hidden population.

At stage l , it first puts the set $\bar{V}^l$ of visited nodes and the set E^l of visited edges to $\emptyset$. Then, for each node $v^l \in V^{l-1}$, it selects k nodes belonging to the neighborhood $v(v^l)$ of v^l uniformly at random or according to some policy, adds them to $\bar{V}^l$ and adds the edges from v^l to each of these nodes to E^l . The methodology to perform the selection of the k nodes may depend on the application context. At the end of stage l , it constructs V^l as $V^l = \bar{V}^l - \cup_{j=0..l-1} V^j$.

The process is repeated for t stages until to the budget B is exhausted.

The final sampled network $\mathcal{N} = \langle V_s, E_s \rangle$ is constructed by setting $V_s = \cup_{j=0..t} V^j$ and $E_s = \cup_{j=1..t} E^j$.

Note that SBS is very similar to BFS. Indeed, the difference is that BFS considers the whole neighborhood of the current node, whereas SBS considers only k nodes of this neighborhood.

Random Walk (RW)

Random Walk starts from an initial node v^0 . Initially, it puts the set $\bar{E}_s$ of visited edges to $\emptyset$. At step l , it chooses one node v_j of the neighborhood $v(v^{l-1})$ of v^{l-1} . This choice can be performed uniformly at random or according to some policy. Then, it sets $v^l = v_j$ and adds to $\bar{E}_s$ the edge from v^{l-1} to v^l .

This process continues for t stages until to the budget B is exhausted. The final sampled network $\mathcal{N}_s = \langle V_s, E_s \rangle$ can be constructed in two different ways, namely:

- By setting $V_s = \{v^0, v^1, \dots, v^t\}$ and $E_s = \bar{E}_s$.
- By setting $\bar{V}_s = \{v^0, v^1, \dots, v^t\}$, $E_s = \cup_{v^l \in \bar{V}_s} t(v^l)$ and $V_s = \{v^l, v_j | (v^l, v_j) \in E_s\}$. In this case, RW reduces to Node Sampling with Neighborhood.

RW is also related to SBS. In fact, it can be considered as a specific case of SBS where $k=1$. However, there is an important difference between them because RW is memoryless. In fact, in SBS, the participants from previous stages are excluded, whereas, in RW, the same node can be visited more times.

It is possible to show that, when RW is applied on an undirected network, it returns a uniform distribution of edges. In this sense, it can be considered equivalent to ES.

Finally, it is worth pointing out that, if the choice of the next node to visit is performed uniformly at random, a node has a degree-proportional probability to be in V_s .

Metropolis-Hastings Random Walk (MHRW)

Metropolis-Hastings Random Walk is capable of returning a desired node distribution from an arbitrary undirected network. It uses two parameters, namely the probability P_{v^l, v_j} to pass from v^l to v_j and the desired distribution δ_v of a node v .

MHRW behaves analogously to RW. However, if v^l is the current node at stage l , the next node v_j to visit is determined according to the parameter P_{v^l, v_j} . The value of this parameter can be determined taking three possible cases into account. Specifically:

- If $v^l \neq v_j$ and $v_j \in \iota(v^l)$, then $P_{v^l, v_j} = M_{v^l, v_j} \cdot \min\left\{1, \frac{\delta_{v_j}}{\delta_{v^l}}\right\}$.
- If $v^l \neq v_j$ and $v_j \notin \iota(v^l)$, then $P_{v^l, v_j} = 0$.
- If $v^l = v_j$ then $P_{v^l, v_j} = 1 - \sum_{v_k \in V_s, v_k \neq v^l} P_{v^l, v_k}$.

Here, $M_{v^l, v_j} = M_{v_j, v^l}$ is a normalization factor for the pair $\langle v^l, v_j \rangle$. It allows the condition $\sum_{v_k \in V_s, v_k \neq v^l} P_{v^l, v_k} \leq 1$ to be satisfied. Since adding more higher-weight self-loops makes the mixing time longer, M_{v^l, v_j} should be selected as larger as possible. A possible choice for it is $M_{v^l, v_j} \min\left\{\frac{1}{|\iota(v^l)|}, \frac{1}{|\iota(v_j)|}\right\}$.

The application scenario of MHRW is more limited than the one of RW. In fact, to calculate P_{v^l, v_j} the degree of the neighboring nodes should be known. This information is often unavailable even if, in some cases, it is fixed (e.g., in P2P) or it can be obtained through a suitable API (e.g., in Online Social Networks).

Random Walk with Escaping (RWE)

Random Walk with Escaping, or Random Jump, is analogous to RW. However, if v^l is the current node, to determine the next node to visit, besides walking to a node of $\iota(v^l)$, RWE can jump to an arbitrary random node $v_j \in V$. RWE is not very meaningful as a sampling technique. Indeed, it is classified as a TBS technique. However, TBS generally operates when the whole network cannot be reached, or at least direct NS or ES is hard. By contrast, RWE needs an efficient NS as a support. As a consequence, it cannot be adopted in several scenarios. Furthermore, it is possible to show that, even when RWE can be adopted, it is hard to construct unbiased estimators for the properties of $\mathcal{N}$ starting from the ones of $\mathcal{N}_s$.

Multiple Independent Random Walkers (MIRW)

One problem of RW is that it tends to be trapped into local dense regions. Therefore, it could have high biases, according to different initial nodes. Multiple Independent Random Walkers was proposed to face this problem. First, it applies NS to choose l initial nodes. Then, it splits the budget B among l Random Walks and let them execute independently from each other. Finally, it merges the results produced by the l Random Walkers. As a matter of facts, it was shown that the estimation errors of MIRW are higher than the ones of MDRW (see Section Multi-dimensional random walk (MDRW)). As a consequence, we have mentioned MIRW only for completeness purposes.

Multi-Dimensional Random Walk (MDRW)

Multi-Dimensional Random Walk, or Frontier Sampling, starts by determining the number k of dimensions. Then, it initializes a list L of nodes by assigning k nodes, determined randomly via NS, to it. After this, it performs several iterations until to the Budget B is exhausted.

During one of these iterations, first it chooses one node v^l from L with the probability $p(v^l)$ proportional to $|\iota(v^l)|$. Then, it selects a node $v_j \in \iota(v^l)$. Finally, it adds the edge (v^l, v_j, w_{ij}) to E_s and substitutes v^l with v_j in L .

It was shown that: (i) MDRW provides very good estimations of some graph properties; (ii) when $l \rightarrow \infty$, MDRW obtains a uniform distributions of both nodes and edges.

Forest Fire Sampling (FFS)

Forest Fire Sampling can be considered as a probabilistic version of Snowball Sampling (see Section Snowball sampling (SBS)). Specifically, in SSB, k neighbors are selected at each round, whereas, in FFS, a geometrically distributed number of neighbors is selected at each round. If the parameter p of the geometric distribution is set to $\frac{1}{k}$, then the corresponding expectation is equal to k and FFS behaves very similarly to SBS.

An important common point between FFS and SBS, which differentiates both of them from RW and its variants, is that, in FFS and SBS, when a node is visited, it will no longer be visited again. By contrast, in RW and its variants, repeated nodes are included in the sample for estimation purposes.

Respondent Driven Sampling (RDS)

The original idea of Respondent Driven Sampling is to run SBS and to correct the bias according to the sampling probability of each node of V_s . Currently, SBS is often substituted by RW because the bias of RW can be more easily corrected. In this case, RDS is also called Re-Weighted Random Walk (RWRW). We point out that, actually, RDS itself is not a standalone network sampling technique. Indeed, it uses SBS or RW for sampling and, then, corrects the corresponding bias.

The principle underlying this approach is the following: it does not matter the adopted sampling technique (NS, ES or TBS); as long as the sample probability is known, the suitable bias correction technique can be invoked.

If we consider sampling and estimating tasks as a whole activity, RWRW and MHRW seem to have the same objective and similar results.

RWRW is a practical approach to estimate several properties without knowing the full graph.

Analysis and Assessment

In this section, we propose a comparison of network sampling approaches as far as network property preservation and network property estimation are concerned. Although these two goals are different, their results are strictly related and can transform to each other.

In the literature, it was shown that the Node Sampling or the Edge Sampling approaches and their variants (i.e., NS, ES, NSN, ESC and NSC) are completely dominated by Traversal Based Sampling approaches across all network features. Among the TBS approaches, there is no clear single winner. Each approach is the best one for at least a network feature of a particular network configuration.

More specifically, it was shown that, in presence of a Poisson degree distribution, approaches as SBS and FFS, configured with the mean of its geometric distribution set to 80% of the number of the remaining unselected neighbors (we call FFS80% this configuration), which can reconstruct a good representation of some local parts of the network nodes, perform relatively well. Furthermore, in presence of a power law degree distribution, approaches as RW and FFS, configured with the mean of the geometric distribution set to 20% of the number of the remaining unselected methods (we call FFS20% this configuration), which explore nodes farther away from the focal ones, perform better.

A closer examination of the approaches provides an, at least partial, motivation of these results. Indeed, SSB tends to return sampled networks, whose degree distributions contain inflated proportions of nodes with the highest and the lowest degrees. Clearly, this causes a poor performance of this approaches when applied to networks with a power-law degree distribution, which are characterized by a small proportion of high-degree nodes. On the contrary, RW tends to return sampled networks, whose nodes never have the highest degrees. Now, since the proportion of nodes with the highest degree is much lesser in the power-law degree distribution than in the Poisson distribution, RW performs better when applied to networks with the former distribution than to networks with the latter one. Furthermore, networks with Poisson distributions tend to be homogeneous throughout their regions; as a consequence, a locally-oriented approach, like SSB, can provide good results. On the contrary, networks with power-law degree distributions require a more global exploration; as a consequence, for this kind of network, FFS and RW appear more adequate.

Summarizing and, at the same time, deepening this topic, we can say that SBS is well suited for sampling social networks with Poisson degree distribution, RW is adequate for sparse social networks with power-law degree distribution and FF is well suited for dense social networks with power-law degree distribution. To implement this recommendation, the knowledge of the degree distribution of network nodes must be known. However, this information may be unavailable in many cases. In the literature, it was shown that FFS presents the best overall performance in determining degree distributions across different kinds of network and sample size. Therefore, it could be useful to exploit an adaptive sampling procedure using different sampling approaches at different stages. For instance, this procedure could start with FFS when no knowledge about the distribution of network nodes is available. Then, after a certain number of nodes have been included in the sample, it is possible to determine the degree distribution of the current sample and, based on it, to continue with FFS or to switch to SBS or RW.

Closing Remarks

In this article, we have provided a general presentation of algorithms for traversing, searching and sampling graphs. We have seen that these algorithms have been investigated very much in the past literature in many research fields. Instead, they were little employed in bioinformatics and biomedicine, where the most important adoption cases regard knowledge classification and motif search. In this article, we have introduced a formalism to represent a complex network, we have provided three taxonomies of sampling approaches, we have presented a brief description of each of them and, finally, we have compared them. We think that network traversing/searching/sampling approaches could have much more usage cases in the future. As a matter of fact, the amount of available data is increasing enormously. This fact could give origin to more and more sophisticated networks. In several cases, it could be impossible to perform the analysis of the whole network; when this happens, the possibility to have some reliable samples of them could be extremely beneficial.

Introduction

Many studies have been performed on graphs modeling the complex interactions occurring among different components in the cell (Atias and Sharan, 2012; De Virgilio and Rombo, 2012; Ferraro *et al.*, 2011; Panni and Rombo, 2015; Pizzuti *et al.*, 2012; Sharan *et al.*, 2007). Most of these studies involve the analysis of graph topology, according to different points of view. In this manuscript, we consider two specific problems based on the analysis of graph topology, that are: Clustering of graphs representing biological networks, and searching for motifs in biological networks.

In particular, an important problem in Biology is the detection of molecular complexes, that can help in understanding the mechanisms regulating cell life, in describing the evolutionary orthology signal (e.g., (Jancura *et al.*, 2011)), in predicting the biological functions of uncharacterized proteins, and, more importantly, for therapeutic purposes. The problem of detecting molecular complexes from biological networks can be computationally addressed using clustering techniques. Clustering consists of grouping data objects into groups (also called *clusters* or *communities*) such that the objects in the same cluster are more similar to each other than the objects in the other clusters (Jain, 1988). Possible uncharacterized proteins in a cluster may be assigned to the biological function recognized for that module, and groups of proteins performing the same tasks can be singled out this way. As observed in Fortunato (2010), a generally accepted definition of “cluster” does not exist in the context of networks, since it depends on the specific application domain. However, it is widely accepted that a community should have more internal than external connections. For biological networks, the most common assumption is that clusters are groups of highly connected nodes, although recently the notion of community intended as a set of topologically similar links has been successfully used in Ahn *et al.* (2010) and Solava *et al.* (2012).

As for the search of motifs, the concept of *motif* has been exploited in different applications of computational biology (Apostolico *et al.*, 2008a,b; Furfaro *et al.*, 2017; Parida, 2008, 2014). Depending on the context, *what is a motif* may assume sensibly different meanings. In general, motifs are always associated to *interesting* repetitions in a given data set. Interestingness is the key concept for the definition of motif; for example, a repetition can be considered interesting when its frequency is greater than a fixed threshold, or instead when it is much different than expected (Apostolico *et al.*, 2003). Also in the context of biological networks, a motif can be defined according to its *frequency* or to its *statistical significance* (Ciriello and Guerra, 2008). In the first case, a motif is a subgraph that appears more than a threshold number of times in an input network; in the second case, a motif is a subgraph that appears more often than expected by chance. In particular, to measure the statistical significance of the motifs, many works compare the number of appearances of the motifs in the biological network with the number of appearances in a number of randomized networks (Erdos and Renyi, 1959, 1960), by exploiting suitable statistical indices such as *p-value* and *z-score* (Milo *et al.*, 2002).

Here we provide a compact overview of the main algorithms and techniques proposed in the literature to solve both clustering and motifs search in biological networks.

Algorithms for Network Clustering

Local Neighborhood Density Search

Many methods, including the most popular, are based on local neighbourhood density search. Their objective is to find dense subgraphs (that is, each node is connected to many other nodes in the same subgraph) within the input network. We summarize in the following seven representative methods in this class.

One of the most popular methods for finding modules in *protein – protein* interaction networks is MCODE (Bader and Hogue, 2003). This method employs a node weighting procedure by local neighbourhood density and outward traversal from a locally dense seed protein, in order to isolate the dense regions according to given input parameters. The algorithm allows fine-tuning of clusters of interest without considering the rest of the network and allows examination of cluster interconnectivity, which is relevant for protein networks. It is implemented as Cytoscape plug-in. With a user-friendly interface, it is suited for both computationally and biologically oriented researchers.

In Altaf-Ul-Amin *et al.* (2006) the DPCLUS method for discovering protein complexes in large interaction graphs was introduced. It is based on the concepts of *node weight* and *cluster property* which are used for selecting a seed node to be expanded by iteratively adding neighbours, and to terminate the expansion process, respectively. Once a cluster is generated, its nodes are removed from the graph and the next cluster is generated using only the remaining nodes until all the nodes have been assigned to a cluster. The algorithm also allows to generate overlapping clusters by keeping the nodes already assigned to clusters.

CFINDER is a program for detecting and analyzing overlapping dense groups of nodes in networks; it is based on the clique percolation concept (see (Adamcsek *et al.*, 2006; Derenyi *et al.*, 2005; Palla *et al.*, 2005)). The idea behind this method is that a cluster can be interpreted as the union of small fully connected sub-graphs that share nodes, where a parameter is used to specify the minimum number of shared nodes.

RANCoC (Pizzuti and Rombo, 2012), MF-PINCoC (Pizzuti and Rombo, 2008) and PINCoC (Pizzuti and Rombo, 2007) are based on greedy local expansion. They expand a single protein randomly selected by adding/removing proteins to improve a given quality function, based on the concept of co-clustering (Madeira and Oliveira, 2004). In order to escape poor local maxima, with a given probability, the protein causing the minimal decrease of the quality function is removed in MF-PINCoC and PINCoC. Instead RANCoC removes, with a fixed probability, a protein at random, even if the value of the quality function diminishes. This strategy is more efficient in terms of computation than that applied in the methods (Pizzuti and Rombo, 2007, 2008), and it is more efficacious in avoiding entrapments in local optimal solutions. All three algorithms work until either a preset of maximum number of iterations has been reached, or the solution cannot further be improved. Both MF-PINCoC and RANCoC allow for overlapping clusters.

DME (Georgii *et al.*, 2009) is a method for extracting dense modules from a weighted interaction network. The method detects all the node subsets that satisfy a user-defined minimum density threshold. The method returns only locally maximal solutions, i.e., modules where all the direct supermodules (containing one additional node) do not satisfy the minimum density threshold. The obtained modules are ranked according to the probability that a random selection of the same number of nodes produces a module with at least the same density. An interesting property of this method is that it allows to incorporate constraints with respect to additional data sources.

Cost-Based Local Search

Methods based on cost-based local search extract modules from the interaction graph by partitioning the graph into connected subgraphs, using a cost function for guiding the search towards a best partition. We describe here in short three methods based on this approach with different characteristics.

A typical instance of this approach is RNSC (King *et al.*, 2004), which explores the solution space of all the possible clusterings in order to minimize a cost function that reflects the number of inter-cluster and intra-cluster edges. The algorithm begins with a random clustering, and attempts to find a clustering with best cost by repeatedly moving one node from a cluster to another one. A list of tabular moves is used to forbid cycling back to previously examined solutions. In order to output clusters likely to correspond to true protein complexes, thresholds for minimum cluster size, minimum density, and functional homogeneity must be set. Only clusters satisfying these criteria are given as the final result. This obviously implies that many proteins are not assigned to any cluster.

Several community discovery algorithms have been proposed based on the optimization of a modularity-based function (see e.g. (Fortunato, 2010)). Modularity measures the fraction of edges falling within communities, subtracted by what would be expected if the edges were randomly placed. In particular, Qcut (Ruan and Zhang, 2008) is an efficient heuristic algorithm applied to detect protein complexes. Qcut optimizes modularity by combining spectral graph partitioning and local search. By optimizing modularity, communities that are smaller than a certain scale or have relatively high inter-community density may be merged into a single cluster. In order to overcome this drawback, the authors introduce an algorithm that recursively applies Qcut to divide a community into sub-communities. In order to avoid over-partitioning, a statistical test is applied to determine whether a community indeed contains intrinsic sub-community.

ModuLand (Kovacs *et al.*, 2010) is an integrative method family for determining overlapping network modules as hills of an influence function-based, centrality-type community landscape, and including several widely used modularization methods as special cases. Several algorithms obtained from ModuLand provide an efficient analysis of weighted and directed networks, determine overlapping modules with high resolution, uncover a detailed hierarchical network structure allowing an efficient, zoom-in analysis of large networks, and allow the determination of key network nodes. It is implemented as Cytoscape plug-in.

Flow Simulation

Methods based on the flow simulation approach mimic the spread of information on a network. We consider three methods based on this approach.

One of the first flow simulation methods for detecting protein complexes in a protein-protein interaction network is the *Markov Clustering algorithm* MCL (Enright *et al.*, 2002). MCL simulates the behaviour of many walkers starting from the same point, that move within the graph in a random way.

Another method based on flow simulation is RRW (Macropol *et al.*, 2009). RRW is an efficient and biologically sensitive algorithm based on repeated random walks for discovering functional modules, which implicitly makes use of network topology, edge weights, and long range interactions between proteins.

An interesting method based on flow simulation is STM (Hwang *et al.*, 2006), which finds clusters of arbitrary shape by modeling the dynamic relationships between proteins of a protein-protein interaction network as a signal transduction system. The overall signal transduction behaviour between two proteins of the network is defined in order to evaluate the perturbation of one protein on the other one, both biologically and topologically. The signal transduction behaviour is modelled using the Erlang distribution.

Statistical Measures

The two following approaches rely on the use of statistical concepts to cluster proteins. They are based on the number of shared neighbours between two proteins, and on the notion of preferential attachment of the members of a module to other elements of the same module, respectively.

Samantha and Liang (2003) proposed a clustering method, here called SL by the names of the authors, based on the idea that if two proteins share a number of common interaction partners larger than what would be expected in a random network, then they should be clustered together. The method assesses the statistical significance of forming shared partnership between a pair of proteins using the concept of p-value of a pair of proteins.

The p-values of all proteins pairs are computed and stored in a similarity matrix. The protein pair with the lowest p-value is chosen to form the first group and the corresponding rows and columns of the matrix are merged in a new row and column. The new p-value of the merged row/column is the geometric mean of the separate p-values of the corresponding elements. This process is repeated by adding new proteins to the actual cluster until a threshold is reached. The process is repeated on the remaining proteins until all the proteins have been clustered.

In Farutin *et al.* (2006) a statistical approach for the identification of protein clusters is presented, here called FARUTIN (the name of the first author). This method is based on the concept of preferential interaction among the members of a module. The authors use a novel metric to measure the community strength. The community strength is gauged by the preferential attachment of each member of a module to the other elements of the same module. This concept of preferential attachment is quantified by how unlikely it is observed in a random graph.

Population-Based Stochastic Search

Population-based stochastic search has been used for developing algorithms for community detection in networks (see e.g., (Pizzuti, 2008; Tasgin and Bingol, 2007)).

In Liu and Liu (2006) the authors proposed an algorithm based on evolutionary computation, here called CGA, for enumerating maximal cliques and apply it to the Yeast genomic data. The advantage of this method is that it can find as many potential protein complexes as possible.

In Ravae *et al.* (2010) an immune genetic algorithm, here called IGA, is described to find dense subgraphs based on efficient vaccination method, variable-length antibody schema definition and new local and global mutations. The algorithm is applied to clustering protein-protein interaction networks

In GA-PPI (Pizzuti and Rombo, 2014a,b) the adopted representation of individuals is the graph-based adjacency representation, originally proposed in Park and Song (1989), where an individual of the population consists of n genes, each corresponding to a node of the graph modeling the protein-protein interaction network. A value j assigned to the i th gene is interpreted as a link between the proteins i and j , and implies that i and j belong to the same cluster. In particular, in Pizzuti and Rombo (2014a) the fitness functions of *conductance*, *expansion*, *cut ratio*, *normalized cut*, introduced by Leskovec *et al.* (2010), are employed, while in Pizzuti and Rombo (2014b) the cost functions of the RNSC algorithm (King *et al.*, 2004) have been used.

Link Clustering

Link clustering methods group the set of edges rather than the set of nodes of the input network, often exploiting suitable techniques to compute edge similarity (Kuchaiev *et al.*, 2011; Milenkovic and Przulj, 2008; Przulj, 2007; Solava *et al.*, 2012). In Evans and Lambiotte (2010), Evans and Lambiotte (2009), Pizzuti (2009) link clustering is used to discover overlapping communities in complex networks different than protein-protein interaction networks. In the following we summarize two link clustering techniques applied to protein-protein interaction networks.

Given an input protein-protein interaction network N , the approach by Pereira *et al.* (2004) builds the corresponding line graph G . In particular, a vertex of G represents an edge of N , and two vertices are adjacent in G if and only if their corresponding edges in N share a common endpoint. Thus, each node of G represents an interaction between two proteins, and each edge represents pairs of interactions connected by a common protein. Pereira *et al.* apply MCL (Enright *et al.*, 2002) on G , and detect this way overlapping protein modules in N .

Ahn *et al.* (2010) propose an agglomerative link clustering approach to group links into topologically related clusters. The algorithm applies a hierarchical method based on the notion of *link similarity*, that is used to find the pair of links with the largest similarity in order to merge their respective communities. The similarity between two links takes into account the size of both the intersection and the union of their neighbourhoods. The agglomerative process is repeated until all the links belong to a single cluster. To find a meaningful community structure, it is necessary to decide where the built dendrogram must be cut. To this end, the authors introduce the concept of *partition density* to measure the quality of a link partitioning, and they choose the partitioning having the best partition density value.

Link clustering approaches have the main advantage that nodes are automatically allowed to be present in multiple communities, without the necessity of performing multiple clustering on the set of edges. As a negative point, if the input network is dense, then link clustering may become computationally expensive. We also observe that the performances of these techniques may depend on the link similarity measure they adopt. This issue is addressed by Solava *et al.* (2012), where a new similarity measure, extending that proposed in by Przulj (2007), has been defined. In particular, this measure is based on the topological

similarity of edges, computed by taking into account non-adjacent, though close, edges and counting the number of graphlets (i.e. are small induced subgraphs containing from 2 up to 5 nodes) each edge touches.

Algorithms for the Search of Motifs in Graphs

Given a biological network N , a *motif* can be defined according to its *frequency* or to its *statistical significance* (Ciriello and Guerra, 2008). In the first case, a motif is a subgraph appearing more than a threshold number of times in N ; in the second case, it is a subgraph occurring more often than expected by chance. In particular, to measure the statistical significance of a motif, many works compare its number of occurrences with those detected in a number of randomized networks (Erdos and Renyi, 1960), by exploiting suitable statistical indices such as *p-value* and *z-score* (Milo et al., 2002).

Milo et al. and its Extensions

The search of significant motifs in biological networks is pioneered by Shen-Orr et al. (2002), where *network motifs* have been defined as “patterns of interconnections that recur in many different parts of a network at frequencies much higher than those found in randomized networks”. The authors of Shen-Orr et al. (2002) studied the transcriptional regulation network of *Escherichia coli*, by searching for small motifs composed by three-four nodes. In particular, three highly significant motifs characterizing such network have been discovered, the most famous is the “feed-forward loop”, whose importance has been shown also in further studies (Mangan and Alon, 2003; Mangan et al., 2005).

The technique presented in Shen-Orr et al. (2002) laid the foundations for different extensions, the main of which are Berg and Lassig (2004), Cheng et al. (2008), Yeager-Lotem et al. (2004).

Milo et al. (2002) generalized the approach presented in Shen-Orr et al. (2002), in order to detect any type of connectivity graph in networks representing a broad range of natural phenomena. In particular, they considered gene regulatory networks, ecosystem food webs (Cohen et al., 1990), in where nodes represent groups of species and edges are directed from a node representing a predator to the node representing its prey; neuronal connectivity networks (Kashtan et al., 2004), where nodes represent neurons (or neuron classes), and edges represent synaptic connections between the neurons; technological networks as sets of sequential logic electronic circuits (Cancho et al., 2001), where the nodes in these circuits represent logic gates and flip-flops.

Also Berg et al. in Berg and Lassig (2004) analyzed the gene regulation network of *E. coli*, following the line of Shen-Orr et al. (2002). In particular, they developed a search algorithm to extract topological motifs called *graph alignment*, in analogy to sequence alignment, that is based on a scoring function. The authors observed that, in biological networks, functionally related motifs do not need to be topologically identical; thus, they discussed motifs derived from families of mutually similar but not necessarily identical patterns. Then, they compare the maximum-likelihood alignment in the *E. coli* data set with suitable random graph ensembles. They considered two different steps, in order to disentangle the significance of the number of internal links, and of the mutual similarity of patterns found in the data.

In Yeager-Lotem et al. (2004) composite network motifs are searched for. Such motifs consist of both transcription regulation and protein-protein interactions that recur significantly more often than in random networks. The authors developed algorithms for detecting motifs in networks with two or more types of interactions. In particular, they modelled an integrated cellular interaction network by two types (colors) of edges, representing protein-protein and transcription-regulation interactions, and developed algorithms for detecting network motifs in networks with multiple types of edges. Such a study may be considered as a basic framework for detecting the building blocks of networks with multiple types of interactions.

The most evolutive extension of Shen-Orr et al. (2002) has been presented in Cheng et al. (2008), where two types of motifs have been defined, that are, *bridge motifs*, consisting of weak links only, and *brick motifs*, consisting of strong links only. In particular, links are considered *weak* or *strong* according to the strength of the corresponding interaction (Girvan and Newman, 2002; Newman, 2003). The authors proposed a method for performing simultaneously the detection of global statistical features and local connection structures, and the location of functionally and statistically significant network motifs. They distinguished *bridge* motifs (consisting of weak links only) and *brick* motifs (consisting of strong links only), observing that brick motifs play a central role in defining global topological organization (Dobrin et al., 2004); bridge motifs include isolated motifs that neither interact nor overlap with other motifs. Cheng et al. examined functional and topological differences between *bridge* and *brick* motifs for predicting biological network behaviors and functions.

Motifs are “Not-Isolated”

In Dobrin et al. (2004) Dobrin et al. studied the transcriptional regulatory network of the bacterium *Escherichia coli*. The authors distinguish *coherent* motifs where all the directed links are activating, from *incoherent* ones, where one of the links inhibits the activity of its target node. They observed that in the analyzed network the vast majority of motifs overlap generating distinct topological units referred to as *homologous motif clusters*; then, they merged all the homologous motif clusters, finding that they form a single large connected component (i.e., *motif supercluster*) in which the previously identified homologous motif clusters are no longer clearly separable.

In Mazurie et al. (2005) the integrated network of *Saccharomyces cerevisiae*, comprising transcriptional and protein-protein interaction data, has been investigated. A comparative analysis has been performed with respect to *Candida glabrata*, *Kluyveromyces lactis*, *Debaryomyces hansenii* and *Yarrowia lipolytica*, which belong to the same class of *hemiascomycetes* as *S. cerevisiae* but span a

broad evolutionary range. The fact that the four analyzed organisms share many functional similarities with *S. cerevisiae* and yet span a broad range of evolutionary distances, comparable to the entire phylum of chordates, make them ideal for protein comparisons. Then, phylogenetic profiles of genes within different forms of the motifs have been analyzed, and the functional role in vivo of the motifs was examined for those instances where enough biological information was available.

Other Approaches Based on Topology Only

In Prill *et al.* (2005) performed an exhaustive computational analysis showing that a dynamical property, related to the stability or robustness to small perturbations, is highly correlated with the relative abundance of small subnetworks (network motifs) in several previously determined biological networks. They argued that robust dynamical stability can be considered an influential property that can determine the non-random structure of biological networks.

In Wernicke (2006), Wernicke presented *MFinder*, an algorithm overcoming the drawbacks of Kashtan *et al.* (2004), where a sampling algorithm to detect network motifs had been proposed, suffering from a sampling bias and scaling poorly with increasing subgraph size. The new approach described in Wernicke (2006) is based on randomized enumeration, and comprises a new way for estimating the frequency of subgraphs in random networks that, in contrast to previous approaches, does not require the explicit generation of random networks.

Chen *et al.* presented *NeMoFinder* (Chen *et al.*, 2006), a network motif discovery algorithm to discover repeated and unique meso-scale network motifs in a large protein-protein interaction network, since many of the relevant processes in biological networks have been shown to correspond to the meso-scale (5 – 25 genes or proteins) (Spirin and Mirny, 2003). The procedure is based on the search of repeated trees, to be exploited for partitioning the input network into a set of graphs, represented by their adjacency matrices. Then, they introduce the concept of *graph cousins* to facilitate the candidate generation and frequency counting processes.

In Grochow and Kellis (Network) an algorithm for discovering large network motifs is presented, based on subgraph query and symmetry-breaking. The size of the considered motifs would exceeds 15, since the exploited a symmetry-breaking technique eliminates repeated isomorphism testing. Such a technique reverses the traditional network-based search at the heart of the algorithm to a motif-based search, which also eliminates the need to store all motifs of a given size and enables parallelization and scaling.

Finally, a tool for the exploration of network motifs, namely, *MAVisto*, is described in Schreiber and Schwabermeyer (2005). Such a tool is based on a flexible motif search algorithm and different views for the analysis and visualization of network motifs, such that the frequency of motif occurrences can be compared with randomized networks, a list of motifs along with information about structure and number of occurrences depending on the reuse of network elements shows potentially interesting motifs, a motif fingerprint reveals the overall distribution of motifs of a given size and the distribution of a particular motif in the network can be visualized.

Approaches Based on Node Colors

The structural motifs defined above treat each component of the biological network as a unique and anonymous entity, ignoring any other useful biological information possibly known about them. In fact, the components are “unlabelled”, allowing for capturing only the topological shapes of the associated subgraphs, but not the biological context in which they occur.

An alternative definition of motif is possible, focusing on the functional nature of the components that form the motif. In such a case, the nodes of the input biological network, as well as the motifs to be searched for, are labelled. Each node label is representative of specific biological properties that can be shared by different nodes in the network. Thus, it is possible to *color* the nodes in such a way that each color is associated to a node class, and nodes with the same color belong to the same class. *Node-colors* motifs may be defined as frequent motifs, where the attention turns to the similarity between the corresponding pairs of nodes composing them.

The first time that colors on nodes have been introduced was in Moon *et al.* (2005), where a colored vertex graph model has been exploited, and different nodes and edges classes are considered. In particular, the class of a node is determined by its color, while the class of an edge is determined by the colors of the two nodes at its ends. The authors focused on protein interaction data, and modelled by nodes in the graph both domains and proteins belonging to such domains. Reflexive edges on domains or proteins indicate that they are self-interacting. Relationships which indicate that some protein has some domain are indicated by dotted lines, while interactions between domains or proteins are indicated by solid lines. The proposed algorithm searches for subgraphs of a given graph whose frequency is substantially higher than that of randomized networks. It first enumerates all of the possible subgraphs, then counts the frequency of each subgraph and finally compares their frequencies with those in randomized graphs. In order to count the frequency of each subgraph efficiently, the authors used a canonical labelling of a graph (McKay, 1978). Two graphs have the same canonically label graph if and only if they are isomorphic to each other.

In Lacroix *et al.* (2006) the authors introduce a definition of motif such that the components of the network play the central part and the topology can be added as a further constraint only. They specialized their approach to metabolic networks, calling the motifs they search for *reaction motifs*, and exploited hierarchical classification of enzymes developed by the International Union of Biochemistry and Molecular Biology (IUBMB) (Webb, 1992) to label the nodes. Then, they work on sets of nodes, instead of subgraphs, escaping in this way the necessity of recurring to subgraphs isomorphism.

In Chen *et al.* (2007) a method called *LaMoFinder* has been presented, to label network motifs with Gene Ontology terms (Asburner *et al.*, 2000) in a protein-protein interaction network. The authors followed the line of Kashtan *et al.* (2004) and Chen *et al.* (2006), first searching for the classes of isomorphic subgraphs that frequently occur in the input network, and then verifying which of

these subgraph classes are also displayed at a much higher frequency than in random graphs. Differently from the previous approaches, Chen *et al.* in [Chen *et al.* \(2007\)](#) exploits a further step, which consists of assigning biological labels to the vertices in the network motifs such that the resulting labelled subgraphs also occur frequently in the underlying labelled input network.

The last approach we discuss here is that presented by Parida in [Parida \(2007\)](#), where an exact three-step approach is presented exploiting the concept of *maximality*, suitably defined from the author in the context of network motifs. In particular, a compact notation has been introduced to handle the combinatorial explosion arising from isomorphisms. Such notation is based on grouping together sets of nodes that can be considered “indistinguishable”. Nodes within the same set, in fact, have the same color, thus each of them can be considered equivalent w.r.t. nodes in another set, and play the same role in the correspondent subgraph topology.

Conclusion

We considered two problems involving the analysis of topology in biological networks: Network clustering, aiming at finding compact subgraphs inside the input graph in order to isolate molecular complexes, and the search of motifs, i.e., sub-structures repeated in the input network and presenting high significance (e.g., in terms of their frequency). We provided a compact overview of the main techniques proposed in the literature to solve these problems.

The last group of techniques we presented for the search of motifs in biological networks, involve approaches that actually are not based on the only topology of the input networks, but they also consider additive information encoded as labels on nodes/edges of the network. This is an important aspect since an emergent trend is the construction of “functional networks” where the information obtained from physical interactions among the cellular components is enriched with functional information, coming from the knowledge of common biological functions of the components, or from their involvement in similar phenotypical effects, such as disorders or diseases. To this respect, also clustering techniques allowing the usage of labels on nodes/edges could be useful, as well as, more in general, analysis techniques able to manage heterogeneous networks, where nodes/edges encoding both components and associations of different types may coexist.

Algorithms for Graph and Network Analysis: Graph Alignment

Luigi Palopoli, Università della Calabria, Cosenza, Italy

Introduction

An important problem in biological network analysis is the comparison of different input networks, usually modelling the physical interactions among cellular components. Biological networks are represented by undirect or direct graphs. For example, protein-protein interaction networks are represented by undirect graphs, since the roles of two interacting proteins linked by an edge in the network are supposed to be equivalent, whereas direct graphs are associated with metabolic networks since chemical reactions have specified directions. However, graph alignment has been considered mainly in the context of undirect graphs, therefore we will refer to undirect graphs in the following if not differently specified.

Graph alignment aims at finding conserved portions of two or several input networks and has been applied to solve several problems involving biological networks. For instance, the alignment of biological networks associated with different organisms can be useful to uncover complex mechanisms at the basis of evolutionary conservations, or to infer the biological meaning of groups of interacting cellular components belonging to organisms not yet well characterized (Sharan and Ideker, 2006). Indeed, network alignment can guide the transfer of biological knowledge from model species to less studied species by highlighting conservation between network regions, thus complementing valuable insights provided by genomic sequence alignment (Faisal *et al.*, 2015).

In this manuscript, we illustrate how graph alignment has been defined in the literature, by distinguishing local alignment, global alignment and by also discussing network querying, that is, a specific instance of graph alignment where a small graph is searched for in another one (Section Ways to formulate Graph Alignment). In Section Algorithms for Graph Alignment we provide a comprehensive overview of the algorithms and techniques proposed in the literature to solve each of the specific considered types of graph alignment. Some of the available software tools implementing the techniques proposed in the literature are illustrated in Section Available Software Tools. A working example is provided in Section A Working Example in order to help understanding the application of the available algorithms for graph alignment. Finally, in Section Conclusion and Open Challenges, we discuss the main emerging research directions on this topic and we draw our conclusions.

The interested reader can find other surveys concerning specific aspects of problems involving graph alignment in Alon (2007), Fionda and Palopoli (2011), Hiram Guzzi and Milenkovic (2017), Panni and Rombo (2015), Sharan and Ideker (2006), and Zhang *et al.* (2008).

Ways to Formulate Graph Alignment

In this section we describe how graph alignment can be defined, according to different formulations of the problem. As already pointed out in the Introduction, we suppose that the input networks are always modelled by undirect graphs, since most of the alignment techniques refer to protein-protein interaction networks. Usually, some criterion is established in order to understand if two nodes (e.g., two proteins) are “similar” and then they can be paired during the alignment process. Different ways to compute node similarity can be adopted: for instance, vocabularies from the Gene Ontology (Ashburner *et al.*, 2000) may be used in order to understand the functional similarity of the cellular components associated with the nodes in the input networks, or the corresponding primary structures (e.g., amino acidic sequences) are aligned and the scores returned by the sequence alignment (e.g., BLAST score (Altschul *et al.*, 1997)) are used to measure the similarity between nodes.

Pairwise and Multiple Alignment

Let N_1 and N_2 be two input networks. The alignment problem consists in finding a set of conserved edges across N_1 and N_2 , leading to a (not necessarily connected) conserved subgraph occurring in both the input networks. In this case, the problem is referred to as *pairwise alignment*. *Multiple alignment* is an extension of pairwise alignment where a set of networks $N_1, \dots, N_n$ is considered in input, and it is usually computationally more difficult to be solved. Many of the algorithms proposed for pairwise graph alignment extend also to multiple alignment. For this reason, in the following subsections, we illustrate the graph alignment formulations by focusing on pairwise alignment.

Global Alignment

Given two graphs N_1 and N_2 in input, the aim of global alignment is that of superimposing them in such a way that a matching score involving both nodes and subgraph topology is maximized.

Fig. 1 Example of global alignment.

Fig. 2 Example of local alignment.

Global alignment returns a unique (possibly, the best one) overall alignment between N_1 and N_2 , in such a way that a one-to-one correspondence is found between nodes in N_1 and nodes in N_2 . The result is made of a set of pairs of non overlapping subgraphs of N_1 and N_2 .

Fig. 1 illustrates an example of global alignment between two simple graphs.

Local Alignment

Local alignment aims at finding multiple, unrelated regions of isomorphism among the input networks, each region implying a mapping independently of the others. Therefore, the computed correspondences may involve overlapping subgraphs.

The output of local network alignment is a set of pairs of (possibly) overlapping subgraphs of the input networks, as illustrated in **Fig. 2**.

Local network alignment may be applied to search for a known functional component, for example, pathways, complexes, etc., in a new species.

A Special Case of Local Alignment: Graph Querying

In some contexts, it may be useful searching for the “occurrences” of a specific, usually small, graph into another bigger graph. A typical application is studying how a specific module of a model organism differentiated in more complex organisms (Ferraro *et al.*, 2011). More in general, this problem “is aimed at transferring biological knowledge within and across species”, (Sharan and Ideker, 2006) since the result subnetworks may correspond to cellular components involved in the same biological processes or performing similar functions than the components in the query. Actually, it can be viewed as a specific formulation of local graph alignment, where one of the input networks is much smaller than the other ones.

In more detail, graph querying consists of analyzing an input network, called *target graph*, searching for subgraphs similar to a *query graph* of interest (see **Fig. 3**).

Algorithms for Graph Alignment

Graph alignment involves the problem of subgraph isomorphism checking, that is known to be NP-complete (Garey and Johnson, 1979). Therefore, the techniques proposed in the literature are often based on approximate and heuristic algorithms. Moreover, it is worth pointing out that in most cases the input networks are of the same kind, e.g., protein-protein interaction networks.

Fig. 3 Example of graph querying.

However, graph alignment can be approached also if the input networks are of different types, leading to a kind of *heterogeneous* alignment. Usually, in these cases, the two input networks are merged and statistical approaches are then applied to extract the most significant subgraphs from the integrated network (Wu *et al.*, 2009).

In the following subsections, we provide an overview of the main algorithms and techniques proposed in the literature to solve the different formulations of graph alignment referred to in the previous section.

Global Alignment

Singh *et al.* (2007) present *IsoRank*, an algorithm for pairwise global alignment of protein-protein interaction networks working in two stages: first it associates a score with each possible match between nodes of the two networks, and then it constructs the mapping for the global network alignment by extracting mutually-consistent matches according to a bipartite graph weighted matching performed on the two entire networks. *IsoRank* has been extended in Singh *et al.* (2008) to perform multiple alignment by approximate multipartite graph weighted matching. In Liao *et al.* (2009) the *IsoRankN* (IsoRank-Nibble) tool is proposed, that is, a global multiple-network alignment tool based on spectral clustering on the induced graph of pairwise alignment scores. In Klau (2009) a graph-based maximum structural matching formulation for pairwise global network alignment is introduced, combining a Lagrangian relaxation approach with a branch-and-bound method. MI-GRAAL (Kuchaiev and Przulj, 2011) can integrate any number and type of similarity measures between network nodes (e.g., sequence similarity, functional similarity, etc.) and finds a combination of similarity measures yielding the largest contiguous (i.e. connected) alignments. In Shih and Parthasarathy (2012) a scalable algorithm for multiple alignment is presented based on clustering methods and graph matching techniques to detect conserved interactions while simultaneously attempting to maximize the sequence similarity of nodes involved in the alignment. Finally, in Mongiov and Sharan (2013) an evolutionary-based global alignment algorithm is proposed, while in Neyshabur *et al.* (2013) a greedy method is used, based on an alignment scoring matrix derived from both biological and topological information about the input networks to find the best global network alignment. *ABiNet* (Ferraro *et al.*, 2010; Ferraro *et al.*, 2011) is an algorithm performing *asymmetric alignment*. In particular, given two input networks, the one associated with the best characterized organism (called *Master*) is exploited as a fingerprint to guide the alignment process to the second input network (called *Slave*), so that generated results preferably retain the structural characteristics of the Master network. Technically, this is obtained by generating from the Master a finite automaton, called *alignment model*, which is then fed with a (linearization of) the Slave for the purpose of extracting, via the Viterbi algorithm, matching subgraphs. *ABiNet* performs both querying and global alignment.

Local Alignment

Kelley *et al.* (2004) propose *PathBLAST*, that is, a procedure for pairwise alignment combining interaction topology and protein sequence similarity. They search for high scoring pathway alignments involving two paths, one for each network, in which proteins of the first path are paired with putative homologs occurring in the same order in the second path. *PathBLAST* is extended in Sharan *et al.* (2005) for multiple alignment, based on the generation of a network alignment graph where each node consists of a group of sequence-similar proteins, one for each species, and each link between a pair of nodes represents a conserved protein interaction between the corresponding protein groups. *PathBLAST* has also been used in Bandyopadhyay *et al.* (2006) to resolve

ambiguous functional orthology relationships in protein-protein interaction networks. In, [Koyuturk et al. \(2006\)](#) a technique for pairwise alignment is proposed based on duplication/divergence models and on efficient heuristics to solve a graph optimization problem. *Bi-GRAPPIN* ([Fionda et al., 2009a,b](#)) is based on maximum weight matching of bipartite graphs, resulting from comparing the adjacent nodes of pairs of proteins occurring in the input networks. The idea is that proteins belonging to different networks should be matched looking not only at their own sequence similarity but also at the similarity of proteins they significantly interact with. *Bi-GRAPPIN* allows for the exploitation of both quantitative and reliability information possibly available about protein interactions, thus making the analysis more accurate. *Bi-GRAPPIN* has been exploited in, [Fionda et al. \(2009a,b\)](#) as a preliminary step to apply a node-collapsing technique to extract similar subgraphs from two input networks. In [Flannick et al. \(2006\)](#) an algorithm for multiple alignment, named *Graemlin*, is presented. *Graemlin* aligns an arbitrary number of networks to individuate conserved functional modules, greedily assigning the aligned proteins to non-overlapping homology classes and progressively aligning multiple input networks. The algorithm also allows searching for different conserved topologies defined by the user. It can be used to either generate an exhaustive list of conserved modules in a set of networks (network-to-network alignment) or find matches to a particular module within a database of interaction networks (query-to-network alignment). In [Denielou et al. \(2009\)](#) the algorithm *C3Part-M*, based on a non-heuristic approach exploiting a correspondence multigraph formalism to extract connected components conserved in multiple networks, is presented and compared with *NetworkBlast-M*, ([Kalaev et al., 2008](#)) another technique recently proposed based on a novel representation of multiple networks that is linear in their size. *NetworkBlast-M* can align 10 networks with tens of thousands of proteins in few minutes. The two latter approaches represent the most efficient techniques proposed in the literature for local multiple alignment. Finally, *AlignNemo* ([Ciriello et al., 2012](#)) builds a weighted alignment graph from the input networks, extracts all connected subgraphs of a given size from the alignment graph and use them as seeds for the alignment solution, by expanding each seed in an iterative fashion.

Graph Querying

Network querying approaches may be divided in two main categories: those searching for efficient solutions under particular conditions, e.g., the query is not a general graph but it is a path or a tree, and other approaches where the query is a specific small graph in input, often representing a functional module of another well characterized organism. *MetaPathwayHunter* ([Pinter et al., 2005](#)) is an algorithm for querying metabolic networks by multi-source trees, that are directed acyclic graphs whose corresponding undirected graphs are trees where nodes may present both incoming and outgoing edges. *MetaPathwayHunter* searches the networks for approximated matching, allowing node insertions (only one node), whereas no deletions are allowed. In [Shlomi et al. \(2006\)](#) and [Dost et al. \(2007\)](#) *QPath* and *QNet* are presented, respectively. *QPath* queries a protein-protein interaction network by a query pathway consisting of a linear chain of interacting proteins belonging to another organism. The algorithm works similarly to sequence alignment, by aligning the query pathway to putative pathways in the target network, so that proteins in analogous positions have similar sequences. Protein-protein interaction networks interactions reliability scores are used, and insertions and deletions are allowed. *QNet* is an extension of *QPath* in which the queries are trees or graphs with limited treewidth. *GenoLink* ([Durand et al., 2006](#)) is a system able to integrate data from different sources (e.g., databases of proteins, genes, organisms, chromosomes) and to query the resulting data graph by graph patterns with constraints attached to both vertices and edges; a query result is the set of all the subgraphs of the target graph that are much similar to the query pattern and satisfy the constraints. In [Yang and Sze \(2007\)](#) the two problems of path matching and graph matching are considered. An exact algorithm called SAGA is presented to search for subgraphs of arbitrary structure in a large graph, grouping related vertices in the target network for each vertex in the query. Although the algorithm is accurate and also relatively efficient to be an exact one, the authors state that it is practical for queries having a number of nodes as large as 20, and its performances improve if the query is a sparse graph. *NetMatch* ([Ferro et al., 2007](#)) is a Cytoscape plugin allowing for approximated queries that come in the form of graphs where some nodes are specified and others are wildcards (which can match an unspecified number of elements). *NetMatch* captures the topological similarity between the query and target graphs, without taking into account any information about node similarities. In [Fionda et al. \(2008\)](#) protein-protein interaction networks are modelled using labelled graphs in order to taken into account interactions reliability, allowing for a rather accurate analysis, and a technique is proposed based on maximum weight matching of bipartite graphs. *Torque* ([Bruckner et al., 2009](#)) is an algorithm based on dynamic programming and integer linear programming to search for a matching set of proteins that are sequence-similar to the query proteins, by relaxing the topology constraints of the query. Finally, we note that, sometimes, methods for local alignment can be also successfully exploited to perform network querying, for example, [Ferraro et al. \(2011\)](#) [Kelley et al. \(2004\)](#) and [Koyuturk et al., 2006](#).

A Working Example

We now illustrate how the alignment tools work by discussing a simple example involving two networks. In particular, we focus on global alignment, and we consider two different approaches: one of the most popular, that is, *IsoRankN*, ([Liao et al., 2009](#)) and one performing asymmetric alignment, that is, *AbiNet* ([Ferraro et al., 2011](#)). The working example reported should allow the reader to understand how the available software tools can be exploited and, moreover, it provides some explanation of the main differences between asymmetric and symmetric alignment.

First of all, it is worth pointing out that interaction data are usually stored in a MiTab format, (Hermjakob *et al.*, 2004) that is a tab-separated text file where each column is associated with specific information, such as the id of interactors, the gene names corresponding to interactors, the experiments in which the interaction was demonstrated, etc. From this file, it is possible to select the information needed to build the networks to be fed to the alignment tools. For both the considered software, the input network can be stored in a tab-separated text file containing only the two columns associated with the interactors. A further file is needed, that is, a *basic dictionary*, storing the similarity score between pairs of nodes in input networks. We assume that the BLAST bit score is used as similarity and we also suppose that only similarity values satisfying a given threshold are kept in the dictionary.

Consider the two input networks Net_1 in Fig. 4(a) and Net_2 in Fig. 4(b). In Fig. 4(c) the input dictionary is reported (where the similarity threshold is set to 40.00).

We run AbiNet by setting first Net_1 and then Net_2 as the Master, and the associations between proteins in the two input networks resulting from the global alignment are shown in Fig. 5(a) and (b), respectively. Then, we run IsoRankN on the same networks and the result is shown in Fig. 5(c).

First of all, note that the three alignments share a central core made of three associations $((p_3, q_3), (p_5, q_5) \text{ and } (p_6, q_6))$, highlighted in bold in Fig. 5. Such associations correspond to a high conservation w.r.t. both protein basic similarity and topology, and this is the reason why they are intercepted in both versions of our Master-Slave alignment and also in the symmetric alignment carried out by IsoRank.

Let us now turn to the differences shown in the three alignment results. Consider the nodes p_2 and p_8 in Net_1 and the node q_2 in Net_2 . Node p_8 has a higher basic similarity to q_2 than p_2 , but p_2 is involved in a larger number of interactions that are *topologically similar* to those involving q_2 . By “topologically similar” we mean interactions in two different networks that involve pairs of proteins with a mutual basic similarity higher than the fixed threshold. As an example, the interaction between p_3 and p_5 in Net_1 can be considered topologically similar to the interaction between q_3 and q_5 in Net_2 . When Net_1 is the Master, the topology of Net_1 is almost completely kept, thus AbiNet associates p_2 with q_2 . On the contrary, when the Master is Net_2 , then the topology around p_2 and p_8 is flattened, and AbiNet associates q_2 with p_8 instead of p_2 , since these two nodes share a higher basic similarity. Looking at all the other discrepancies between the two alignments returned by AbiNet, it is easy to see that the situation is analogous to the

Fig. 4 (a) The input network Net_1 . (b) The input network Net_2 . (c) The input dictionary of protein basic similarities.

Node in Net_1	Node in Net_2	Node in Net_1	Node in Net_2
p_2	q_2	p_3	q_3
p_3	q_3	p_8	q_2
p_5	q_5	p_5	q_5
p_6	q_6	p_6	q_6

Table 1 List of the publicly available software tools implementing the considered techniques for graph alignment

Method	Year	Problem	Software
PathBLAST (Kelley <i>et al.</i> , 2004)	2003	LA, GQ	http://www.pathblast.org/
MetaPathwayHunter (Pinter <i>et al.</i> , 2005)	2005	GQ	http://www.cs.technion.ac.il/olegro/metapathwayhunter/
NetworkBLAST (Sharan <i>et al.</i> , 2005)	2005	LA	http://www.cs.tau.ac.il/~bnet/networkblast.htm
Graemlin (Flannick <i>et al.</i> , 2006)	2006	LA	http://graemlin.stanford.edu/
NetMatch (Ferro <i>et al.</i> , 2007)	2007	GQ	http://ferrolab.dmi.unict.it/netmatch.html
IsoRank (Singh <i>et al.</i> , 2007)	2007	GA	http://groups.csail.mit.edu/cb/mna/
SAGA (Yang and Sze, 2007)	2007	GQ	http://www.eecs.umich.edu/saga
Torque (Bruckner <i>et al.</i> , 2009)	2009	GQ	http://www.cs.tau.ac.il/~bnet/torque.html
IsoRankN (Liao <i>et al.</i> , 2009)	2009	GA	http://groups.csail.mit.edu/cb/mna/
NATALIE (Klau, 2009)	2009	GA	http://www.mi.fu-berlin.de/w/LiSA/Natalie
C3Part-M (Denielou <i>et al.</i> , 2009)	2009	LA	http://www.inrialpes.fr/helix/people/viari/lxgraph/
AbiNet (Ferraro <i>et al.</i> , 2011)	2010	GA, GQ	http://siloe.deis.unical.it/ABiNet/
MI-GRAAL (Kuchaiev and Przulj, 2011)	2011	GA	http://bio-nets.doc.ic.ac.uk/MI-GRAAL/
AlignNemo (Ciriello <i>et al.</i> , 2012)	2012	LA	http://www.bioinformatics.org/alignnemo
NETAL (Neyshabur <i>et al.</i> , 2013)	2013	GA	http://www.bioinf.cs.ipm.ir/software/netal

one we just described. This confirms what we expected, that is, the network exploited as the Master “guides” the alignment. In particular, given a node of the Master, the topology around it is kept and it is associated to a node in the Slave sharing both a high basic similarity and some topologically similar interactions. Since the Slave is linearized, then less importance is given to the topology around the Slave candidate nodes and this can influence the final result. Obviously, there are cases for which these differences are immaterial (as for nodes in the core of Fig. 5), and the same associations are anyway returned.

As for the result returned by IsoRankN, we observe that it agrees with that of the first execution of AbiNet for the association (p_7, q_7), while it agrees with the second execution of AbiNet for the association (p_8, q_2). Furthermore, according to IsoRankN, node p_{11} can be equally associated with q_8 and with q_9 , while AbiNet associates p_{11} with q_8 when Net_1 is the Master and with q_9 when the Master is Net_2 . Finally, we observe that, in both executions, AbiNet is able to arrange at least one node more than IsoRankN (p_2 when Net_1 is the Master and q_1, p_4 when the Master is Net_2). In conclusion, a symmetric alignment can be viewed in part as a “mix” between the two asymmetric ones but, in this case, separating what of a network is more conserved in the other one is not easy.

Available Software Tools

In Table 1, the main software tools implementing the techniques proposed in the literature for graph alignment and discussed in the previous section are summarized. In particular, for each method it is specified the year in which it has been published, the

specific formulation of graph alignment it refers to (we denoted global alignment by “GA”, local alignment by “LA” and graph querying by “GQ”) and the web link where it is possible to access it.

Conclusion and Open Challenges

In this manuscript, we illustrated the problem of graph alignment, and the algorithms for its solution according to different formulations, by referring to the context of biological networks.

Looking at the number of techniques proposed in the literature to solve graph alignment, we can conclude that the problem has been now well studied and an analyst who needs to perform the alignment of biological network data can use several software tools that are publicly available.

However, biological networks intrinsically suffer of the difficulty in collecting an adequate amount of interaction data, therefore the biological results obtained by the alignment between different networks are seriously affected by the partiality of the information given in input. Very few model organisms have been extensively characterized and, even for them, the available interaction networks are far to be complete. Furthermore, to increase the coverage, methods used to reveal interactions have been automated to generate high throughput approaches, which, unfortunately, produce a significant fraction of false positives and reduce the accuracy of the data (von Mering *et al.*, 2002).

In this context, an interesting task would be that of applying techniques in order to both clean and make more accurate the available interaction networks. To this aim, the reliability scores provided by some of the interaction databases might be used, as well as additional information coming from curated vocabularies (e.g., the Gene Ontology (Ashburner *et al.*, 2000)).

A further open challenge is the alignment of “functional” networks, obtained as the integration of information coming from both physical interactions (e.g., protein-protein interactions) and functional annotations (e.g., coming from the Gene Ontology, or from genotype-phenotype associations). In this case the difficulty would be given not only by the heterogeneity of the input networks, which are made of nodes and edges of different types, but also by the very large sizes of the input networks, requiring the application of suitable classification and/or compression techniques, (Furfaro *et al.*, 2017; Hayashida and Tatsuya, 2010) or of big data technologies, that are not yet largely exploited for graph alignment.

Introduction

A big amount of data is generated nowadays and consequently the necessity of storing and querying them is impelling. Bioinformatics can be defined as “the application of computational tools to organize, analyze, understand, visualize and store information associated with biological macromolecules” (Luscombe *et al.*, 2001; Pevsner, 2015). Three main perspectives defined from Pevsner (2015) about the field of bioinformatics and genomics are:

- The cell and the central dogma of molecular biology;
- The organism, which shows changes between the different stages of development and regions of the body;
- The tree of life, in which millions of species are grouped into three evolutionary branches. A computational view is presented by Luscombe (Luscombe *et al.*, 2001).

Goals of bioinformatics are to organize data so that researchers can access the information and create new entries.

- To develop tools and resources that help in the data analysis;
- To use these tools to analyze data and interpret them significantly.

Finally, the issues involved in bioinformatics (Fig. 1) can be classified into two classes: The first related to sequences and the second related to biomolecular structures (Diniz and Canduri, 2017).

Structural Bioinformatics

Several bioinformatics management systems exist and are usually classified according to the type of data (e.g., proteins, genes, transcriptome). Structural bioinformatics databases offer relevant features for the analysis of available information about particular biomacromolecules, for example, their 3D structure, sequence variations, function annotation, intrinsic flexibility, ligand binding cavity identification, interactions with ligands, membrane and subcellular localization (Koča *et al.*, 2016). Protein structural bioinformatics studies the role of the protein in structural, enzymatic, transport, and regulatory functions in the cell. Protein functions are implied by their structures:

Fig. 1 Some of the bioinformatics applications. Figure modified from Diniz, W.J.S, Canduri, F., 2017. Bioinformatics: An overview and its applications. *Genetics and Molecular Research* 16 (1). (gmr16019645).

- Primary structures, arising from the sequence of amino acids residues;
- Secondary structures, (α -helices and β -sheets) that are the repeated main chain conformation stabilized by hydrogen bonds. Their prediction can be determined by short-range interactions representing the formation of α -helices and by long-range interactions characterizing the β -strands. Two methods can be used to predict secondary structures. The first is ab initio-based, which makes use of statistical calculations of the residues of a single query sequence while the second is homology-based, which makes use of common secondary structural patterns conserved among multiple homologous sequences;
- Tertiary structures, which are the three-dimensional conformation of a polypeptide chain and its determination can be obtained using X-ray crystallography and nuclear magnetic resonance spectroscopy;
- Quaternary structures, which are the complex arrangement of multiple polypeptide chains.

Once the structure of a particular protein is solved, a table of (x, y, z) coordinates representing the spatial position of each atom in the structure is created. The coordinate information is then submitted to the Protein Data Bank (PDB) repository, which uses the PDB format to store the structural details and other metadata (authors, publication details, experiment setup). PDB is a worldwide repository of protein structures being currently managed by the Research Collaboratory for Structural Bioinformatics and empowering extensive Structural Bioinformatics investigations also on protein–DNA interfaces. For instance, in Mount (2004); Gardini *et al.* (2017), the modes of protein binding to DNA have been explored by dividing 629 nonredundant PDB files of protein–DNA complexes into separate classes for structural proteins, transcription factors, and DNA-related enzymes.

Another important research area is structural and functional genomics. The first aims to study genomes referring to the initial phase of genome analysis (construction of genetic and physical maps of a genome, identification of genes, annotation of gene features, and comparison of genome structures) whereas the second refers to the analysis of global gene expression and gene functions in a genome. The latter is also called transcriptomics and uses either sequence- or microarray-based approaches (Xiong, 2006). Many genomes have been published because of the reduced costs in sequencing experiments. However, the new methodologies share the size and quality of the reads (150–300 bp) as a limitation, which represents a challenge for assembly software (Miller *et al.*, 2010). On the other hand, they produce much more sequences (Altmann *et al.*, 2012). Making sense of millions of sequenced base pairs is required in order to assemble the genome. The assembly consists of a hierarchical data structure that maps the sequence data to a supposed target reconstruction (Miller *et al.*, 2010). When a genome is sequenced, two approaches may be adopted: If the species' genome was previously assembled, (reference) mapping with the reference genome is performed. However, if a new genome has not been previously characterized, (de novo) assembly is required (Pevsner, 2015). Fig. 2 shows the typical steps for assembling a genome. The sequencer records sequencing data as luminance images captured during DNA synthesis. Therefore, the calling base refers to the acquisition of image data and its conversion into a DNA sequence by FASTA (Diniz and Canduri, 2017). Also, the quality of each base, called Phred score (Altmann *et al.*, 2012), is obtained. Quality control refers to the quality evaluation of the sequenced reads (Phred score) and the filtering of low quality bases and adapter sequences. Assembling each of the reads is mapped to each other while searching for identity or overlapping regions to construct contiguous fragments corresponding to the overlap of two or more reads (Staats *et al.*, 2014).

Fig. 2 Flowchart of genome assembly: De novo and based on the reference genome. Figure modified from Diniz, W.J.S, Canduri, F., 2017. Bioinformatics: An overview and its applications. Genetics and Molecular Research 16 (1), gmr16019645.

Management of the Information and Databases

Health Care Information Systems deliver value to individual health care organizations, patients, and providers, as well as during follow-up for entire communities of individuals (Wager *et al.*, 2017; Coronel and Morris, 2017). According to the latest update, published in January 2017, there exist 1739 biological databases. The information sources used by bioinformaticians can be divided into

- Raw DNA sequences;
- Protein sequences;
- Macromolecular structures;
- Genome sequencing.

Public databases store a big amount of information, and they are usually classified into primary and secondary databases (Diniz and Canduri, 2017). Primary databases are composed of experimental results and researchers submit nucleotide sequences, protein sequences, or macromolecular structures directly in this archive. Secondary databases contain more curated data (called content curation process) and a complex combination of computational algorithms and manual analysis are used to interpret and compile the public record of science.

GenBank is a primary database managed by the National Center for Biotechnology Information (NCBI). It was created in 1982 and has been growing at an exponential rate, almost doubling every 14 months. It contains nucleotide sequences obtained from volunteers and is part of the International Nucleotide Sequence Database Collaboration (INSDC) consortium, together with two other large databases: European Molecular Biology Laboratory (EMBL-Bank), and DNA Data Bank of Japan (DDBJ), in whose National Institute of Genetics archives contain over 110 million sequences each (Pevsner, 2015; Prosdocimi *et al.*, 2002). NCBI is the American database, a subsidiary of the National Library of Medicine. Compared to the EMBL of the European Bioinformatics Institute (EBI), which is a center for research and service in bioinformatics containing sequences of DNA, proteins, and macromolecules structures, NCBI also offers the possibility to perform bibliographic searches and to have a direct link between various biological databases obtaining sequence structure genetic article maps (Fig. 3). Thus, users can access sequences, maps, taxonomic information, and structural data of macromolecules. PubMed is an online repository that allows access to 9 million citations in MEDLINE. BLAST is a program developed at the NCBI that allows one to perform very fast similarity searches on whole DNA databases. DDBJ started its activity in 1984 and it is mainly used by Japanese researchers, but it is accessible worldwide through the Internet and together with the EBI and the NCBI, it is part of the International DNA Databases.

Protein Information Resource (PIR), UniProtKB/Swiss-Prot, PDB, Structural Classification of Proteins 2 (SCOP), and Prosite are secondary databases. They are curated and present only information related to proteins, describing aspects of their structures, domains, functions, and classification. In EMBL and DDBJ annotations are very limited, and there may be multiple entries for the same genes. If a sequence encodes a protein, the conceptual translation, or coding sequence, is shown together with a reference to the NCBI protein database.

Universal Protein Resource is a database managed by EBI, the Swiss Institute of Bioinformatics (SIB), and PIR. UniProtKnowledgeBase (UniProtKB) is one of the most complete sources of information on protein sequences and functions. It consists of the Swiss-Prot and TrEMBL sections: Swiss-Prot is manually curated, with very rich annotations while TrEMBL is automatically annotated and contains the conceptual translations of nucleic acid sequences with minor adjustments. Sequences are stored in TrEMBL before being manually annotated and transferred to SwissProt. UniProt Reference clusters groups closely linked sequences in a single document to speed up searches. UniProt archive is a huge parking lot of protein sequences and stores their history and evolution,

Fig. 3 International nucleotide data banks.

together with all the available related data. The PDB contains the structures of proteins and other biological macromolecules, and provides a variety of resources for the study of their sequences, their functions, and their possible pathological effect ([The UniProt Consortium, 2017](#)).

GenomeNet ([Kotera et al., 2015](#)) is a Japanese network of biocomputational data and services, created in 1991 and managed by the Kyoto University Bioinformatics Center, which hosts the KEGG portal (Kyoto Encyclopedia of Genes and Genomes), which includes gene and protein databases (KEGG genes), chemical components (KEGG ligand), molecular interactions and networks of biochemical reactions (KEGG pathway), of relationships of genomes with the external environment (KEGG brite).

Expert Protein Analysis System proteomics, created in 1993 by the SIB in Switzerland, offers a variety of IT tools for the analysis of protein data and hosts databases of sequences, domains and protein families, proteomic data, models of protein structures, and metabolic pathways ([Gasteiger et al., 2003](#)).

The main genome portals are Ensembl in Great Britain, created jointly in 1999 by the EBI and the Wellcome Trust Sanger Institute; and UCSC Genome Browser, in the United States, created in 2000 at the University of California, Santa Cruz ([Cunningham et al., 2015](#)).

Reference Sequence (RefSeq) by the NCBI is a large collection of annotated sequences that are more restricted. Unlike GenBank, in fact, RefSeq provides just one example of each biological molecule for the major organisms. RefSeq is limited to about 10,000 organisms, while GenBank has sequences obtained from about 250,000 different organisms ([Pruitt et al., 2007; 2014](#)).

The Third Party Annotation database allows authors who publish new experimental evidence to re-record sequences contained in the INSDC database. It is significantly smaller (about one sequence every 12,000) than GenBank ([Benson et al., 2008](#)).

The microRNA database (miRBase) is the central repository for microRNA sequences, very short RNA portions of about 21 nucleotides that seem to play an important role in gene regulation. MicroRNAs control the translation of mRNAs (messenger RNA) of numerous genes and have an important part in cell differentiation and proliferation, in the plasticity of the synapses of the nervous system and in various diseases, including cancer. miRBase hosts sequences of almost 11,000 microRNAs from 58 different species, treats the nomenclature and annotation, and provides computerized prediction programs for target mRNAs ([Kozomara and Griffiths-Jones, 2014](#)).

Research laboratories and scientific journals maintain widely used knowledge portals, which gather information on particular biological problems and provide IT tools to explore them. We report some of them created in the United States. Online Genes to Cognition (G2C), created in 2009 by the Cold Spring Harbor Laboratory, is a neuroscience portal focused on cognitive processes, related diseases, and research approaches ([Croning et al., 2009](#)). Nature Publishing Group hosts Omics gateway, for genomic-scale biology, and The Signaling Gateway (managed together with the University of California, San Diego), focused on signal transduction. *Science* magazine has developed *Science Signaling*, oriented on cellular regulation and signaling, which also maintains a database and various analysis tools organized in dynamically generated diagrams.

Databases of sequence motifs are needed to identify features that indicate specific functions (e.g., catalytic site). It has been observed that genes or proteins that perform a similar function have a similarity in some regions of their sequence. Thus, genes and proteins belonging to the same functional family should contain in their sequence a recurrent motif that characterizes the family and distinguishes it from others. The presence of such signatures is extremely useful to assign a new sequence to a specific family of genes or proteins, and thus to formulate hypotheses about its function.

PROSITE is a database of protein domains, families, and functional sites, integrated with IT tools to identify sequence motifs. It contains specific signatures for more than 1500 protein families and domains with extensive documentation on their structure and function. Through the computational tools hosted by PROSITE (e.g., ScanProsite) or other resources (such as PPSearch of the EMBL-EBI), it is possible to quickly identify which known protein family a given protein sequence belongs to [Hulo et al. \(2006\)](#).

The JASPAR database stores DNA sequences that regulate gene expression (promoters) located before the start of gene transcription sites and binding a variety of regulatory proteins, called transcription factors. The particular combination of factors related to the promoter determines whether the gene will be switched on or off. JASPAR contains 174 distinct pattern patterns representing preferential DNA binding sites of transcription factors, derived from scientific literature and carefully annotated, which can be used to scan genomic sequences ([Sandelin et al., 2004](#)).

Chemical Entities of Biological Interest at the EMBL site, KEGG compound (in the aforementioned GenomeNet network), and Public Chemical database, in the NCBI portal, are databases providing a molecular entities vocabulary, for millions of small chemical substances of biological interest, and descriptions of their structure and their activity ([Kim et al., 2016](#)).

Algorithms and Access to the Data

The choice of comparison algorithms should be based on the desired comparison type, the available computational resources, and the research goals. A rigorous implementation of the Smith–Waterman (SW) algorithm is available, as well as the FASTA program, within the FASTA package. The SW algorithm is one of the most sensitive but it also is computationally demanding. The FASTA algorithm is faster, and its sensitivity is similar to SW in many scenarios ([Brenner et al., 1998](#)). The fastest algorithm is BLAST (Basic Local Alignment Search Tool), the newest versions of which supports gapped alignments and provides a reliable and fast option (the older versions were slower, detected fewer homologs, and had problems with some statistics). Iterative programs like PSI-BLAST require extreme care with their options, as they can provide misleading results; however, they have the potential to find more homologs than purely pairwise methods ([Higgins and Taylor, 2000](#)). In order to achieve higher alignment performances, both the BLOSUM (BLOCKs of amino acid

Substitution Matrix) and the PAM (Point Accepted Mutation) scoring matrices can be used (Dayhoff *et al.*, 1978; Pevsner, 2009; Prosdociimi *et al.*, 2002), which relate the probability of substitution of one amino acid or nucleotide with another due to mutations (the best possible alignment will be one that maximizes the overall score (Junqueira *et al.*, 2014).

Comparative molecular modeling refers to the modeling of the 3D structure of a protein from the structure of an homologous one whose structure has already been previously determined (Capriles *et al.*, 2014). This approach is based on the fact that evolutionarily related sequences share the same folding pattern (Calixto, 2013). The access to biological information could be possible also by searching data banks of networks and models. The most common databases of networks and models are: CO-exPRESsed gene database (COXPRESdb), molecular InteAction database (IntAct), Human Protein Reference Database, Biomolecular Interaction Networks Database, Reactome, KEGG, GO, GeneNetWorks, KWS Online (Java Web Simulation), BioModels and Database Of Quantitative Cellular Signaling. Gene expression can be used to access Ensembl and UCSC Genoma Browser, Project ENCODE (ENCyclopedia of DNA Elements). Finally, Gene Expression Omnibus (GEO) by NCBI and ArrayExpress by EBI, store data in the standardized Minimum Information About a Microarray Experiment format and have online exploration tools (Davis and Meltzer, 2007). Besides hosting many transcriptomic experiments, they host data on the expression of microRNAs, genomic hybridizations, single nucleotide polymorphisms, chromatin immunoprecipitation and peptide profiles. The Allen Brain Atlas contains the three-dimensional, genomic-scale map of the expression of thousands of genes in all areas of the adult mouse brain and in the course of development, down to the cellular level (Hawrylycz *et al.*, 2014).

Data Elaboration

Data mining is the process of learning data with information technology in order to identify hidden structures in the data that allow one to obtain useful information (knowledge discovery) and to make accurate predictions on the evolution of a phenomenon (prediction). The data mining process takes place in several stages: The initial exploration, the construction of a model, and the execution of algorithms. The data mining process attempts to learn something meaningful from the data by highlighting models or groups of objects with similar characteristics. An important distinction is between learning with and without supervision. In the second case, no a priori question is asked about how to divide the data, and learning takes place without specific knowledge about the contents.

In bioinformatics, the unsupervised learning methods cannot be used wherever the biological problem lacks previously known classifications. There are several unsupervised techniques: Hierarchical grouping, k-means, principal component analysis, correspondence analysis and neural networks. Supervised learning, on the other hand, applies to cases in which a particular classification is already known for the training set and we want to build a model that predicts this classification in a new sample. There are various supervised techniques, including decision trees, discriminant analysis, support vector machines and neural networks (Witten *et al.*, 2017).

Expression cluster analysis denotes a number of unsupervised learning algorithms that distribute objects in groups according to similarity criteria where the number of groups can be determined automatically or chosen by the user. The similarity between objects is evaluated through a distance measure: The less objects are distant, the more similar they are and the more easily they will be assigned to the same group. There exist various distance measures, such as the Euclidean distance, which is simply the geometric distance in the multidimensional data space, or the Pearson correlation coefficient, which is a statistical similarity measure. In bioinformatics, an important problem is the extraction of information from large-scale gene expression data obtained by microarrays. The most common approach to gene expression data analysis is the hierarchical grouping, or tree grouping, whereby the relationships between genes are represented by a tree structure in which the proximity of the branches reflects their degree of similarity. The number of groups (clusters) is determined automatically by the algorithm. Sometimes it is convenient to divide the objects into a number of groups of choice, in which case the k-means algorithm can be used, in which attributes are represented as vectors and each group is represented by a point called centroid. The algorithm follows an iterative procedure in which objects are moved between groups in order to minimize the intragroup and maximize the intergroup one until the algorithm converges to a stable solution.

In many data mining problems, neural networks are adopted for their ability to approximate a large family of functions (Cybenko, 1989; Hornik *et al.*, 1989). Generally, neural networks are models used to implement supervised classification techniques. They are able to predict new observations on specific variables, after a learning phase on the preexisting data. The first step is to design the architecture of the network (layers), whose nodes are called neurons. Designing an optimal architecture for the network is not a trivial task, since it heavily depends on the problem and the statistics of the dataset. During training the weights of the network are updated until the examples shown to the network in the input layer give the desired result on the output layer giving a fitting with the desired error. After training, the network is ready to be used to generate predictions about new data. There also exist unsupervised neural networks, called self-organizing neural networks or Kohonen networks (Sarstedt and Mooi, 2014).

Pattern recognition is often performed using probabilistic models such as hidden Markov models, which are suitable to recognize event sequences (e.g., recognition of spoken language, manual writing). In bioinformatics, such models are widely used to identify homologies or to predict coding regions in the genome sequence and protein folding. They derive their name from the chain of Markov, a succession of states in which the transition from a present state to a future takes place with a probability that depends on the present state or from the past. Present state is useful to predict future behavior, while previous history gives insights about the trend of the signal. Markov's theory of processes is often used to give an order to web pages in an Internet search. For instance, Google uses the PageRank

algorithm to assign a numeric weight to web pages, in order to measure their relative relevance. The algorithm is based on the concept of popularity, that is on the frequency with which web pages and online documents are referenced (Zucchini *et al.*, 2016).

Algorithms for Data Elaboration

Statistical and mathematical techniques useful for the exploration of biological data are also adopted by various commercial packages (Wu *et al.*, 2014). MATLAB (MATrixLABoratory) has a section dedicated to bioinformatics tools that allow one to analyze and visualize genomic and proteomic data, and to build models of biological systems. There are specific programs for analyzing microarrays data, for example, GenePix, or for proteomic analysis. R is a widely used open source software environment, and also a software language, within which a variety of statistical and graphical techniques are available (e.g., linear and nonlinear modeling, classical statistical tests, time series analysis tools, classification and grouping algorithms). The tool can be expanded with a vast library of tools obtainable through the CRAN (Comprehensive R Archive Network) repository. Bioconductor provides tools for the analysis of genomic data written in the R language.

Use Cases

RNA-sequencing (RNA-seq) is currently the leading technology for genome-wide transcript quantification. While the volume of RNA-seq data is rapidly increasing, the currently publicly available RNA-seq data is provided mostly in raw form, with small portions processed nonuniformly. This is mainly because the computational requirements, particularly for the alignment step, are a significant barrier for the analysis. To address this challenge RNA-seq and ChIP-seq sample and signature search (ARCHS4) have been created. They are a web resource containing the majority of previously published RNA-seq data from human and mouse at the gene count level. Such uniformly processed data enables easy integration for analyses in various application contexts. For developing the ARCHS4 resource, all available FASTQ files from RNA-seq experiments were retrieved from the GEO, aligned and stored in a cloud-based infrastructure. A total of 137,792 samples are accessible through ARCHS4, with 72,363 mouse and 65,429 human samples. Through the efficient use of cloud resources, the alignment cost per sample has been dramatically reduced. ARCHS4 is updated automatically by adding newly published samples to the database as they become available (Lachmann *et al.*, 2017).

Another example of use of data mining in the bioinformatics scientific literature is biomarkers prediction, such as the prediction and diagnosis of diabetes mellitus (DM). Research efforts have been made to discover and suggest novel biomarkers and finally predict key aspects of the disease, such as its onset, with the bioinformatics tools described above. In general, the arising gaps and limitations of machine learning research in DM are closely related to the availability of data (Kavakiotis *et al.*, 2017).

New Frontiers

The role of data analytics in establishing an intelligent accounting function is to create the insights that help in making better corporate decisions. As organizations develop and adopt technologies related to big data, cognitive computing and the Internet of Things (IoT) applications are growing in both volume and complexity but also new opportunities arise (Pan *et al.*, 2015).

Biographical Sketch

Mariaconcetta Bilotta has achieved a PhD in Biomedical Engineering at the University Magna Graecia of Catanzaro (IT) and now is a biomedical engineer at the Institute S. Anna of Crotona (IT). During the PhD has been visiting student at the WISB (Warwick Center for the Integrative Synthetic Biology) of the University of Warwick, Coventry (UK). Her research interests are modeling and analyzing chemical reactions, design and realization of control systems, synthetic and systems biology, embedded feedback control, automation and robotics in rehabilitation, neurorehabilitation of trunk, microRNA analysis, and health informatics.

Giuseppe Tradigo is a postdoc at the DIMES Department of Computer Science, Models, Electronics and Systems Engineering, University of Calabria, Italy. He has been a Research Fellow at University of Florida, Epidemiology Department, US, where he worked on a GWAS (Genome-Wide Association Study) project on the integration of complete genomic information with phenotypical data from a large patients dataset. He has also been a visiting research student at the AmMBio Laboratory, University College Dublin, where he participated to the international CASP competition with a set of servers for protein structure prediction. He obtained his Ph. in Biomedical and Computer Science Engineering at University of Catanzaro, Italy. His main research interests are big data and cloud models for health and clinical applications, genomic and proteomic structure prediction, data extraction and classification from biomedical data.

Pierangelo Veltri is associate professor in bioinformatics and computer science at Surgical and Clinical Science Department at University Magna Graecia of Catanzaro. He got his PhD in 2002 from University of Paris XI, and worked as researcher at INRIA from 1998 to 2002. His research interests regard database management systems, data integration, biomedical data management, health informatics. He has coauthored more than 100 papers, and he is editor of ACM SIGBioinformatics newsletter and associate editor of *Journal of Healthcare Informatics Research*.

Data Storage and Representation

Antonella Guzzo, University of Calabria, Rende, Italy

Data Storage of Biomedical Data

In the last decade, several techniques for biological data analysis and manipulation have been developed, including, methods for rapid genomic and RNA sequencing, mass spectrometry, microarray, yeast two-hybrid assay for protein–protein interactions, X-ray crystallography and NMR for protein structures. Moreover, due to these techniques, an enormous amount of biomedical data has been generated. In fact, to have an idea of the volume of data storage that these techniques have to deal with, we can just observe that, for the genomics alone, the first 20 of the largest biomedical institutions (Zachary *et al.*, 2015) currently consume more than 100 petabytes of storage. Moreover, it is estimated that by 2025 the data-storage demands for this application could run to as much as 2–40 exabytes (1 exabyte is 10¹⁸ bytes). Table 1 mentions just three of the most popular databases and their main characteristic.

As a matter of fact, the availability of this enormous amount of data raises important challenges in terms of scalability, complexity and costs of big data storage infrastructure. At the same time, privacy and security are important issues to be taken into account, too. For instance, the most immediate consequence of dealing with such enormous volume of data is, from a practical point of view, that the traditional way for bioinformatics analysis, involving to download the data from public sites (e.g., UCSC (Rosenbloom *et al.*, 2015) and Ensembl (Bronwen *et al.*, 2016)), to install software tools locally, and to run analysis on in-house computer resources is obsolete and evolving toward new and more efficient solutions and approaches. A specific solution approach that is practicable for data storage and transfer is a type of Dropbox for data scientists named Globus Online (Foster, 2011; Allen *et al.*, 2012), which provides storage capacity and secure solutions to transfer the data.

However, large amounts of data require also higher computational infrastructures, as High Performance Computing clusters (HPCs), that not only provide storage solutions but also parallel processing of computational tasks over the stored data. In fact, solutions based on HPCs tend to be difficult to maintain and lead to extremely high costs. A relatively more practical solution to handle big data is the usage of *cloud computing* infrastructures. Cloud computing exploits the full potential of multiple computers and delivers computation and storage as dynamically allocated virtual resources via the Internet. Specifically, bioinformatics clouds (Dai *et al.*, 2012) involve a large variety of services from data storage, data acquisition, and data analysis, which in general fall into four categories: (1) Data as a Service (like public datasets of Amazon Web Services (AWS) (Murty, 2009)) enables dynamic data access on demand and provides up-to-date data that are accessible by a wide range of Web applications; (2) Software as a Service delivers software services online and facilitates remote access to available bioinformatics software tools through the internet; (3) Platform as a Service (like Eoulsan (Jourdren *et al.*, 2012), the cloud-based-for high-throughput sequencing analyses and Galaxy Cloud (Afgan *et al.*, 2011), the cloud-scale-for large-scale data analyses) offers an environment for users to develop, test and deploy cloud applications where computer resources scale automatically and dynamically to match application demand, avoiding to know how many resources are required or to assign resources manually in advance and (4) Infrastructure as a Service (like Cloud BioLinux (Krampis *et al.*, 2012), the virtual machine that is publicly accessible for high-performance bioinformatics computing and CloVR (Angiuoli *et al.*, 2011), the portable virtual machine that incorporates several pipelines for automated sequence analysis) offers a full computer infrastructure by delivering all kinds of visualized resources via the internet, including hardware (e.g., CPUs) and software (e.g., operating systems). Fig. 1 shows the general abstract architecture of bioinformatics clouds.

Despite the advantages of bioinformatics clouds, in particular, despite the possibility for users to access visualized resources as a public utility and pay for the cloud resources that they utilize, only a tiny amount of biological data is accessible in the cloud at present (only AWS, including GenBank, Ensembl, 1000 Genomes, etc.), while the vast majority of data are still deposited in conventional biological databases. Another weakness in full exploiting the potentiality of the bioinformatics clouds is that transferring vast amounts of biological data to the cloud is a significant bottleneck in cloud computing. With this respect, it must be observed that choosing a proper data representations can drastically reduce the required storage and consequently the band of communication if data are transmitted over network, and impacts over the computation time obviously.

The data representation adopted by the most well-known public databases of biological data was initially just a sequence data, with some annotation within a text file format. With the introduction of the XML standard for data representation, a plethora of

Table 1 Few popular databases and their volume

Database	Description	Volume
ArrayExpress	Functional genomics data	45.51 TB of archived data
GenBank	Sequence data in term of DNA	213 billion nucleotide bases in more than 194 million sequences
Protein Data Bank (PDB)	Crystallographic db for 3-D structural data	More of 118192 released structures

Fig. 1 Categorization of bioinformatics clouds. Reproduced from Dai, L., Gao, X., Guo, Y., *et al.*, 2012. Bioinformatics clouds for big data manipulation. *Biology Direct* 7, 43.

pseudostandards for XML biological data storage have been developed by different public databases, beginning with the flat file format of FASTA, moving to the Genbank and Swiss-Prot formats, and ending to the pure XML format – a review of these formats is behind the scope of this article, so that interested readers are referred to [Shahzad *et al.* \(2017\)](#) for a complete survey on modern data format. To our ends, instead, it is interesting to observe that, very recently, it is emerging the idea of using Synthetic DNA for data Storage and, in fact, several researchers have come up with a new way to encode digital data in the base sequence of DNA to create the highest-density large-scale data storage scheme. Unfortunately real applications are limited so far by high cost and errors in the data, while in a recent study researchers announced they have made the process error-free and 60 per cent more efficient compared to previous results, approaching the theoretical maximum for DNA storage ([Bornholt *et al.*, 2016](#)).

Beside the specific data format compliant with the different databases, it is relevant to discuss here some data model adopted for representing biological data, which come as single and/or multiple abstractions allowing us to carry out a large number of data processing and task analysis.

Basic Data Models for Biological Data

Background

To begin the discussion of data model representation, basic terms and concepts should be first introduced. Three are the key components in everything related to life: deoxyribonucleic acid (DNA), ribonucleic acid (RNA), and proteins.

DNA is the basic hereditary material in all cells and contains all information, parts of DNA called genes, code for proteins which perform all the fundamental processes for living using biochemical reactions. The genetic information is represented both by DNA and RNA. In fact, while cells use only DNA, some viruses, the retroviruses, have their genome encoded into the RNA, which is replicated into the infected cells. The central dogma of molecular biology was first enunciated by Francis Crick in 1958 and re-stated in a paper appeared in the *Nature* journal published in 1970. It states that biological function is heavily dependent on the biological structure and it deals with the detailed residue-by-residue transfer of sequential information. Thus, it states that information cannot be transferred back from protein to either protein or nucleic acid. In other words, the central dogma of molecular biology is that genes may perpetuate themselves and work through their expression in form of proteins, but it is not possible to go the other way around and obtain the gene sequence from the protein. Note that the expression of a gene is its product, that is, the protein for which the gene encodes information.

The genetic information is encoded into the sequence of the bases of the DNA and perpetuate through the replication. This is represented by a loop in the [Fig. 2](#) from DNA to DNA, meaning that the molecules can be copied. Transcription, the next arrow, is

Fig. 2 The schematic central dogma.

Fig. 3 Different levels of protein structures. Google images

the process by which the enzyme (that is a protein working as a biochemical catalysator) RNA polymerase, reads the sequence of bases on a gene and constructs an mRNA molecule from that sequence. Translation, the last arrow, is the process by which a ribosome, a macromolecular assembly, reads the information contained in the mRNA molecule and synthesizes a protein molecule from the sequence on the mRNA molecule. Thus, each protein molecule is a product of the gene that codes for it. In turn, proteins are responsible for carrying out various functions inside the cell. For instance, many proteins work as enzymes that catalyze the reactions that occur in living organisms or they can interact with other molecules for performing storage and transport functions. Moreover, these fundamental components provide mechanical support and shape to mechanical work as, for example, muscular contraction. Finally, several proteins have an essential role in the decoding of cellular information and also regulate the transcription of a gene to an mRNA molecule. Recently, it is worth observing that relations from RNA to DNA are also considered and studied, by capturing the mechanism via which retrovirus can copy their RNA genomes into DNA.

From a biological point of view, RNA is a polymer that contains ribose rather than deoxyribose sugars. The normal base composition is made up of guanine, adenine, cytosine, and uracil. Proteins are macromolecules composed by linear polymers, or chains, of amino acids. All organisms use the same set of 20 amino acids as building blocks in the protein synthesis. The variations of the order in which amino acids are connected and their total number let to obtain an almost unlimited number of proteins. The DNA uses four nucleotides: adenine (A), guanine (G), cytosine (C) e thymine (T). Since it is not possible to represent each of the 20 different amino acid by a nucleotide, each amino acid corresponds to a group of nucleotides. By choosing words composed by two nucleotides only a few number of combinations can be obtained. Instead, by choosing words composed by three nucleotides many more combinations can be obtained, that are sufficient to encode the 20 amino acids. Thus, a code of three or more nucleotides is necessary and the one made of three nucleotides seems to be valid for all organisms. Each triplet is called codon. All the 64 codons specify amino acids except three of them, that are stop triplets, and are stop signals in the transduction process. Since 61 codons are used to encode 20 amino acids, multiple triplets may encode for the same amino acid, and in general these have the same first two nucleotides and different third nucleotides. The starting triplet is the one encoding the methionine amino acid: all proteins start with this amino acid. The transduction process ends and the protein is released when one of the three stop triplets is recognized. The 20-amino acids are composed by an amide group and a carboxylic group, also known as α -carbon. The α -carbon also binds hydrogen atoms and a side chain. The side chain is distinctive to each amino acid. The amino acids are bound to one another by the condensation of a α -carboxylic group of one amino acid to the amide group of another amino acid to form a chain. This bound is known as peptidic bound and the involved amino acids are called residues. The free amide and carboxylic groups at the opposite extremities of the peptidic chain are called *N*-terminal (amide terminal) and *C*-terminal (carboxylic terminal). Conventionally, all the residues of a peptidic chain are numbered starting from *N*-terminals.

On the basis of protein complexity, a protein can have at most four levels of structural organization (see [Fig. 3](#)). The primary structure of a protein is the sequence of its amino acids, forming the polypeptidic chain, describing the one-dimensional structure of the protein. The other three levels encode the protein three-dimensional structure. In more detail, the polypeptidic chain patterns that regularly repeats into the protein denote the secondary structure. The tertiary structure is related to the three-dimensional structure of the whole polypeptide. The quaternary structure is related to the arrangement of two or more polypeptidic chains in one polymer. Alterations of the conditions of the environment, or some chemical treatments, may lead to a destruction of the native conformation of proteins with the subsequent loosing of their biological activities. This process is called denaturation. Proteins have different functions; they can provide structure (ligaments, fingernails, hair), help in digestion

(stomach enzymes), aid in movement (muscles), and play a part in our ability to see (the lens of our eyes is pure crystalline protein).

Strings and Sequences for Representing Biomolecules (DNA and Proteins)

Many biological objects can be interpreted as strings. As already pointed out in the previous subsection, biologically a strand of DNA is a chain of nucleotides adenine, cytosine, guanine, and thymine. The four nucleotides are represented by letters A, C, G, and T, respectively. Thus, a strand of DNA can be encoded as a string built from a 4-letter alphabet A, C, G, T, corresponding to the four nucleotides. Formally, let $\mathcal{A} = \{A, C, G, T\}$ be an alphabet and let k be a integer with $k \geq 1$, we call *DNA k -words* a string of length k over the letters A, C, G, and T. Specifically, let $\mathcal{W}_k$ be the set of all possible k -words formed using the alphabet $\mathcal{A}$, the size of $|\mathcal{W}_k|$ being 4^k . Moreover, for $k=1$ each 1-words denotes one of the four DNA bases (individual nucleotides), for $k=2$ each 2-words denotes one of the $|\mathcal{W}_k|=4^2=16$ possible dinucleotides (AA, AC, AG, AT, CA, ...), for $k=3$ each 3-words denotes a one of the $|\mathcal{W}_k|=4^3=64$ possible codons (AAA, AAC, ...). For $k \geq 4$, a k -words is a generic sequence that can have biological interest. It is possible that the biologists cannot determine some nucleotides in a DNA strand. In this case, the character N is used to represent an unknown nucleotides in the DNA sequence of the strand. In other words, N is a wildcard character for any one character among A, C, G, and T. A DNA sequence is an *incomplete sequence* if the corresponding strand contains one or more character N ; otherwise, it is said a *complete sequence*. A complete sequence is said to agree with an incomplete sequence if it is a result of substituting each N in the incomplete sequence with one of the four nucleotides. For example, ACCCT agrees with ACNNT, but AGGAT does not.

Similarly, proteins can also be seen as strings. In fact, we define a protein as the linear sequence of its amino acids. Formally, let $\mathcal{A}_p = \{a_1, \dots, a_j\}$ be a set of strings, where a_i encodes an amino acid recognized in a protein structure. Then, each protein can be represented by a string over the alphabet $\mathcal{A}_p$, where every letter in the alphabet correspond to a different amino acid. The total number of the recognized amino acids is 20 and thus the size of the $\mathcal{A}_p$ -alphabet is 20, too. Each protein sequence has a length varying from several tens to several thousands and usually contains long repeated sub-sequences. Moreover each protein sequence codes protein molecules, but not every string over the amino acid alphabet codes real protein molecules (Kertesz-Farkas, 2008). The amino acid sequence of a protein is determined by the gene that encodes for it. The differences between two primary structures reflect the evolutive mutations. The amino acid sequences of related species are, with high probability, similar and the number of differences in their amino acid sequences are a measure of how far in the time the divergence between the two species is located: the more distant the species are the more different the protein amino acid sequences are. The amino acid residues, essential for a given protein to maintain its function, are conserved during the evolution. On the contrary, the residues that are less important for a particular protein function can be substituted by other amino acids. It is important to note that some proteins have a higher number of substitutable amino acids than others, thus proteins can evolve at different speeds. Generally, the study of molecular evolution is focused on family of proteins. Proteins belonging to the same family are called homologous and the tracing of the evolution process starts from the identification of such families. Homologous are identified by using specialized amino acids sequence alignment algorithms that, by analyzing two or more sequences, search for their correspondences.

Recent studies have demonstrated that is easier to detect that two proteins share similar functions based on their structures rather than on their sequences. As a consequence, more attention is currently paid to the structural representation instead of the sequence one, and in fact there has been a growing interest in finding and analyzing similarities between proteins, with the aim of detecting shared functionality that could not be detected by sequence information alone.

Structures for Representing Biomolecules

The secondary structure of a protein is referred to the general three-dimensional form of local segments of proteins. It does not describe specific atomic positions in three-dimensional space, but is defined by patterns of hydrogen bonds between backbone amide and carboxylic groups. The secondary structure is related to the spacial arrangement of amino acid residues that are neighbors in the primary structure. The secondary structure is the repetition of four substructures that are: α helix, β sheet, β turn, Ω loop. The most common secondary structures are alpha helices and beta sheets (see Fig. 4). A common method for determining protein secondary structure is far-ultraviolet (far-UV, 170–250 nm) circular dichroism. A less common method is infrared spectroscopy, which detects differences in the bond oscillations of amide groups due to hydrogen-bonding. Finally, secondary-structure contents may be accurately estimated using the chemical shifts of an unassigned NMR spectrum.

The tertiary structure of a protein is its three-dimensional structure, as defined by the atomic coordinates. The function of a protein is determined by its three-dimensional structure and the three-dimensional structure depends on the primary structure. Efforts to predict tertiary structure from the primary structure are generally known as protein structure prediction. However, the environment in which a protein is synthesized and allowed to fold are significant determinants of its final shape and are usually not directly taken into account by current prediction methods.

The biological activity of a protein is related to the conformation the protein assumes after the folding of the polypeptidic chain. The conformation of a molecule is a spacial arrangement that depends on the possibility for the bonds to spin. In physiologic conditions a protein has only one stable conformation, known as native conformation.

On the contrary of secondary structure, the tertiary structure also takes into account amino acids that are far in the polypeptidic sequence and belong to different secondary structures but interact with one another. To date, the majority of known protein

Fig. 4 Two examples of protein secondary structure: α helix and β sheet.

Fig. 5 An example of protein tertiary structure. Uniprot database

structures have been determined by the experimental technique of X-ray crystallography. A second common way of determining protein structures uses NMR, which provides somewhat lower-resolution data in general and is limited to relatively small proteins.

An example of tertiary structure as reported by the PDB database (see Relevant Website section) (Rose *et al.*, 2017) is shown in Fig. 5. The figure represents the tertiary structure of the *S-Adenosylmethionine Synthetase* with 8-BR-ADP.

Many proteins are assembled in more than one polypeptide chain, known as protein subunits. In addition to the tertiary structure of the subunits, multiple-subunit proteins possess a quaternary structure, which is the three-dimensional spatial arrangement of the several polypeptidic chains, corresponding to protein subunits. According to this structure, proteins can be subdivided in two groups: homo-oligomers and hetero-oligomers. The first group is made of proteins composed by only one type of subunit, while the second one is made of proteins that are composed by different types of subunits. The proteins belonging to the first group are those having structural and supporting roles, while the proteins belonging to the second one have dynamic functions.

Protein quaternary structures can be determined using a variety of experimental techniques that require a sample of proteins in a variety of experimental conditions. The experiments often provide an estimate of the mass of the native protein and, together

**Fig. 6** An example of protein quaternary structure. Uniprot database

with knowledge of the masses and/or stoichiometry of the subunits, allow the quaternary structure to be predicted with a fixed accuracy. However, it is not always possible to obtain a precise determination of the subunit composition. The number of subunits in a protein complex can often be determined by measuring the hydrodynamic molecular volume or mass of the intact complex, which requires native solution conditions.

Table 2 reports the nomenclature used to identify protein quaternary structures. The number of subunits in an oligomeric complex are described using names that end in *-mer* (Greek for “part, subunit”).

Fig. 6 shows an example of the quaternary structure of a protein. The quaternary structure reported in the figure is a *tetramer* and is related to a potassium ion channel protein from *Streptomyces lividans*.

The quaternary structure is important, since it characterizes the biological function of proteins when involved in specific biological processes. Unfortunately, quaternary structures are not immediately deducible from protein amino acid sequences.

Biological Networks as Expressive Data Models

Graph Theory

Biological networks are data structures used to store information about molecular relations and interactions. Usually, they are conveniently represented as graphs (Huber *et al.*, 2007). A undirect graph $\mathcal{G}$ is a pair $\mathcal{G} = \langle V, E \rangle$, where V is the set of nodes and E is the set of edges $E = \{\{i, j\} | i, j \in V\}$, so that the elements from E are subsets of elements of V . A direct graph is defined as a pair $\mathcal{G} = \langle V, E \rangle$ where, instead, elements in E are ordered pairs – so that if $E = (i, j)$, then i is considered the source node and j a target node. The ordered pairs of vertices are called directed edges, arcs or arrows.

In graph-based system biology, nodes of the graph represent cellular building blocks (e.g., proteins or genes) and the set of edges represent interactions (see Fig. 7). Specifically, each edge represents a mutual interaction in the case of undirected graph, while, conversely, the flow of material or information from a source node to a target node, in a directed graph.

In computational biology, we usually use weighted graphs, that is a graphs $\mathcal{G} = \langle V, E \rangle$ associated with a weight function $w: E \rightarrow \mathbb{R}$, where $\mathbb{R}$ denotes the set of all real numbers and the weight w_{ij} represents the relevance of the connection among the nodes i and j . As an example, relations whose importance varies are frequently assigned to biological data to capture the relevance of co-occurrences identified by text mining, sequence or structural similarities between proteins or co-expression of genes (Jensen *et al.*, 2009; Lee *et al.*, 2014). Different types of graphs are used to represent different types of biological networks, each of which stores information about interactions related to specific entities or molecules.

Relevant kinds of networks include: transcriptional regulatory networks, signal transduction networks, metabolic networks, protein-protein interaction networks (or PPI network), domain interaction networks, Gene Co-Expression Networks and genetic interaction networks. Some of these networks will be discussed in the rest of the section.

Protein-Protein Interaction (PPI) Networks

PPI are powerful models to represent the pairwise protein interactions of the organisms, such as building of protein complexes and the activation of one protein by another protein. Their visualization aids biologists in pinpointing the role of proteins and in gaining new insights about the processes within and across cellular processes and compartments, for example, for formulating and experimentally testing specific hypotheses about gene function (Pavlopoulos *et al.*, 2011). A PPI network is common represented as a directed graph $\mathcal{G} = \langle V, E \rangle$ with an associated function t , where V is the set of proteins, E the set of directed interactions, and t a function $t: E \rightarrow T$ which defines the type of each edge (interaction type). PPI networks can be derived from a variety of large biological databases that contain information concerning PPI data. Some well-known databases are the Yeast Proteome Database (YPD) (Hodges *et al.*, 1999), the Munich Information Center for Protein Sequences (MIPS) (Mewes *et al.*, 2004), the Molecular Interactions (MINT) database (Zanzoni *et al.*, 2002), the IntAct database (Kerrien *et al.*, 2007), the Database of Interacting Proteins (DIP) (Xenarios *et al.*, 2000), the Biomolecular Interaction Network Database (BIND) (Bader *et al.*, 2009), the BioGRID database (Stark *et al.*, 2006), the Human Protein Reference Database (HPRD) (Keshava Prasad *et al.*, 2009), and the HPID (Han *et al.*, 2004) and the DroID (Yu *et al.*, 2008) database for Drosophila.

Regulatory Networks

This kind of network contains information about the control of gene expression in cells. Usually, these networks use a directed graph representation in an effort to model the way that proteins and other biological molecules are involved in gene expression

Fig. 7 Examples of graph structures.

and try to imitate the series of events that take place in different stages of the process. They often exhibit specific motifs and patterns concerning their topology. Databases collecting Protein-DNA interaction data are listed as follow: JASPAR ([Sandelin et al., 2004](#)), TRANSFAC ([Wingender et al., 1996](#)) or B-cell interactome (BCI) ([Lefebvre et al., 2007](#)), while post-translational modification can be found in databases like Phospho. ELM ([Diella et al., 2004](#)), NetPhorest ([Miller et al., 2008](#)) or PHOSIDA ([Gnad et al., 2007](#)).

Signal Transduction Networks

This kind of networks uses a graph representing both protein interactions and biochemical reactions, and their edges are mostly directed, indicating the direction of signal propagation ([Pavlopoulos et al., 2011](#); [Ma'ayan et al., 2005](#)). Often, these networks use multi-edged directed graphs to represent a series of interactions between different bioentities such as proteins, chemicals or macromolecules and to investigate how signal transmission is performed either from the outside to the inside of the cell, or within the cell.

Environmental parameters change the homeostasis of the cell and, depending on the circumstances, different responses can be triggered. Similarly to GRNs, these networks also exhibit common patterns and motifs concerning their topology ([Pavlopoulos et al., 2011](#)). Databases that store information about signal transduction pathways are MiST ([Ulrich and Zhulin, 2007](#)), TRANSPATH ([Krull et al., 2003](#)).

Metabolic and Biochemical Networks

This kind of networks is the complete network of metabolic reactions of a particular cell or organism, for example to produce energy or synthesize specific substances. A metabolic pathway is a connected sub-network of the metabolic network either representing a series of chemical reactions occurring within a cell at different time points ([Pavlopoulos et al., 2011](#); [Jeong et al., 2000](#)). The main role within a metabolic network is played by the enzymes, since they are the main determinants in catalyzing biochemical reactions. Often, enzymes are dependent on other cofactors, such as vitamins for proper functioning. The collection of pathways, holding information about a series of biochemical events and the way they are correlated, is called a metabolic network. Modern sequencing techniques allow the reconstruction of the network of biochemical reactions in many organisms, from bacteria to human ([Ma et al., 2007](#)). Some well-known databases collecting information about biochemical networks are listed as follow: the Kyoto Encyclopedia of Genes and Genomes (KEGG) ([Kanehisa et al., 2010](#)), EcoCyc ([Keseler et al., 2009](#)), BioCyc ([Karp et al., 2005](#)) and metaTIGER ([Whitaker et al., 2009](#)).

Evolutionary Trees and Networks

Hierarchical networks are considered in molecular biology. In particular, phylogenetic/evolutionary trees represent the ancestral relationships between different species, and thus they are widely used to study evolution, to describe and explain the history of species, i.e., their origins, how they change, survive, or become extinct ([Pavlopoulos et al., 2011](#)). Formally, a phylogenetic tree $T = (V, E, \delta)$ is a triple consisting of a set of nodes V (taxons), a set edges $E = V \times V$ (links) and a function δ mapping edges to real numbers, quantifying the biological divergence between the target node, for example, biological time or genetic distance. A node in the tree can be a leaf node representing species, sequences, or similar entities; on the other hand, it can be an internal node representing (hypothetical) ancestors generated from phylogenetic analysis. Phylogenetic trees are often stored in the Newick file format ([Cardona et al., 2008](#)), which makes use of the correspondence between trees and nested parentheses.

Databases that store phylogenetic information are TreeBASE ([Roderic, 2007](#)), which stores all kinds of phylogenetic data (e.g., trees of species, trees of populations, trees of genes) representing all biotic taxa, and TreeFam ([Li et al., 2006](#)), a database of phylogenetic trees of gene families found in animals.

As an extension of tree, we have phylogenetic networks that provide an explicit representation of the evolutionary relationships among sequences, genes, chromosomes, genomes, or species. They differ from phylogenetic trees because of the explicit modeling, by means of hybrid nodes instead of only tree nodes, of reticulate evolutionary events such as recombination, hybridization, or lateral gene transfer, and differ also from the implicit networks that allow for visualization and analysis of incompatible phylogenetic signals ([Huson and Bryant, 2006](#)).

Finally, signal transduction, gene regulatory, protein-protein interaction and metabolic networks interact with each other and build a complex network of interactions; furthermore, these networks are not universal but species-specific, i.e., the same network differs between different species.

Closing Remarks

We have described data storage methods for biological data. In particular, we have discussed basic data models and more advanced ones, namely biological networks, with special emphasis on PPI networks, regulatory networks, metabolic networks and evolutionary networks.

Experimental Platforms for Extracting Biological Data: Mass Spectrometry, Microarray, Next Generation Sequencing

Barbara Calabrese, University "Magna Graecia", Catanzaro, Italy

© 2019 Elsevier Inc. All rights reserved.

Introduction

Omics refers to the characterization of pools of biological molecules (i.e., nucleic acids, proteins, metabolites). Omics studies have developed rapidly thanks to technological advances in high-throughput technologies, such as mass spectrometry, microarray and next generation sequencing, in the last two decades.

Microarray technology allows researchers to assess thousand of genes, proteins or other analytes through a variety of means. In addition to this technology, next-generation sequencing allows the sequencing of nucleic acids in millions of parallel reactions. Moreover, advancements in other technologies, such as mass spectrometry, enable researchers to collect data and gain major knowledge on biological and cellular processes.

The development of these technologies have led to a production of a vast amount of complex and multidisciplinary data that pose new challenges in terms of management, analysis and interpretation.

Mass Spectrometry

Mass spectrometry is a methodology aiming to (i) determine the molecular weight of a large variety of molecules and biomolecules (peptides, proteins), (ii) provide structural information on proteins, and on their post-translational modifications and (iii) carry out quantitative analysis of both small molecules and of biomolecules, providing high sensitivity and high specificity. Mass spectrometric measurements are carried out in the gas phase on ionized analytes (Aebersold and Mann, 2003). Specifically, molecules are ionized and then introduced into an electrical field where they are sorted by their mass to charge ratio (m/z). Thus, a mass spectrometer consists of an ion source, a mass analyzer that measures the mass-to-charge ratio of the ionized analytes and a detector, that registers the number of ions at each m/z value.

The two most common techniques to ionize the sample are:

- MALDI (Matrix Assisted Laser Desorption Ionization): a laser is used to ionize and vaporize a small amount of sample, which is then drawn into the mass spectrometer for analysis;
- ESI (Electrospray Ionization): a stream of liquid containing the sample is ionized by applying an electrical charge to it. This creates a stream of ions which repel each other upon exiting the capillary tubing creating a fine plume of ions which is then drawn into the mass spectrometer for analysis.

There are different types of mass analyzer (Matthiesen and Bunkenborg, 2013). One common is the quadrupole. This consists of 2 pairs of charged rods. There is an electrical potential between each pair of rods which draws the ions towards one rod. The polarity of this electrical field is oscillated rapidly, which causes the ions travel through the quadrupole in a spiral trajectory. Each oscillation frequency allows ions with a particular m/z to pass through, while the other ions crash into the poles and lose their charge, or are ejected from the quadrupole. By varying the oscillation frequency, ions with different m/z ratios will get through. The number of ions passing through at any given frequency is measured by the mass spectrometer's detector and a graph of intensity vs. m/z is created from this data. An MS Spectra represent the abundance of each ion as a function of its mass, i.e., the final mass spectrum, that is a long sequence of pairs of values ($i, m/z$), where i is the intensity or abundance and m/z is the mass of each detected molecule. Spectra are normally represented as histograms that report the abundance of each ion as a function of its mass, reasonably assuming that all the ions produced by the analysis have a single charge. The abundances are reported as a ratio to the base peak, which is the most abundant peak observed in the spectrum. This normalization allows to have spectra that are a function only of the analyte and of the conditions of analysis.

Another component used to filter ions is the ion trap. In an ion trap ions are collected and held either in a 3-dimensional space or a 2-dimensional plane. Once a certain number of ions have been collected, or after a set time, the ions are ejected from the trap. This ejection voltage is ramped in a way that allows different m/z ions to be ejected at slightly different times. This time difference creates an MS Spectra. Because a greater number of ions is collected, this method typically has a higher sensitivity than using a quadrupole mass filter.

One more common method of sorting ions is the Time-of Flight or TOF analyzer. In this analyzer the ions are collected in a similar manner to an ion trap, and then accelerated with one push into an empty chamber with an electrical field in it. The chamber is at a very low pressure, usually about $1 \cdot 10^{-7}$ torr, this allows the ions to fly freely with few collisions with other molecules. The ions are reflected by the electrical field (ion mirror) into a detector. Because larger m/z ions take longer to be turned around in the electrical field they arrive at the detector later, allowing for the creation of a MS Spectra. Because of the way the ions are sorted this method of analysis has high mass accuracy (Walther and Mann, 2010).

Tandem Mass Spectrometry

ESI and MALDI generate ions causing minimal fragmentation in molecules. This implies that the only information available from the analysis is a more or less accurate measurement of the molecular weight analyte. This is not sufficient for a detailed characterization structure of peptides and proteins (primary structure, modifications post-translational). It is necessary to use Tandem Mass Spectrometry, that consists in carrying out a double mass analysis on a given sample (Han *et al.*, 2008). To do this, it is possible to use two analyzers in series, or use the same analyzer at different times. It is an important technique, better known as MS/MS: the protein is pretreated with a chemical reagent to obtain various fragments, the mixture is injected into an instrument that is two spectrometers placed in series. The spectrometer consists of an MS-1 chamber which has the task of selecting among the various ions the desired one. The selected ion is put in contact with a gas (it can be of helium) in the collision cell. From the impact between the gas and the ion, fragments are obtained, which are separated into the MS-2 chamber, based on the mass to charge ratio.

This means that each group contains all the fragments loaded, due to the breaking of the same type of bond, even if in different positions, so that each successive peak has an amino acid less than that which precedes it. The difference in mass between one peak and another one identifies the amino acid that has been lost and therefore the peptide sequence. Through this method it is possible to catalog separate cell proteins through electrophoresis.

Peptide Mass Fingerprinting (PMF)

Peptide Mass Fingerprinting (PMF), also known as mass fingerprinting, was developed in 1993. It is a high throughput protein identification technique in which the mass of an unknown protein can be determined. PMF is always performed with Matrix-assisted laser/desorption ionization time of flight (MALDI-TOF) mass spectrometry (Thiede *et al.*, 2005).

Peptide means protein fragment, which is often generated by trypsin, mass means the molecular size of peptides and the fingerprinting presents the uniqueness of the masses of peptides. This technique means that the digestion of a protein by an enzyme can provide a specific fingerprint of great specificity, which can possibly identify the protein from this information alone.

In this technique, after separation of proteins by gel electrophoresis or liquid chromatography and being cleaved with a proteolytic enzyme, it is possible to get experimental peptide mass through mass spectrometry. On the other hand, the theoretical masses are achieved by using computer programs that translate the known genome of the organism into proteins or the proteins in the database, then theoretically cut the proteins into peptides, and calculate the absolute masses of the peptides. The experimentally obtained peptide masses are compared with theoretical peptide mass. The results are statistically analyzed to find the best match.

There are several steps for PMF:

- Protein separation: the proteins of interest from a sample are separated by gel electrophoresis.
- Digestion: the protein of interest is digested by the proteolytic enzyme. Trypsin is the favored enzyme for PMF. It is relatively cheap, highly effective and generates peptides with an average size of about 8–10 amino acids, which is suitable for MS analysis.
- Mass Spectrometric analysis: the peptides can be analyzed with different types of mass spectrometers, such as MALDI-TOF or ESI-TOF. The mass spectrometric analysis produces a peak list, which is a list of molecular weights of the fragments.
- In silico digestion: software performs in silico digestion on database proteins with the same enzyme used in the experimental digestion and generates a theoretical peak list. Mascot, MS-Fit, and Profound are the most frequently used search programs for PMF.
- Comparison: in this step, it is performed a comparison between peak list and theoretical peak list to get best match.

Microarray

A DNA microarray (commonly known as gene chip, DNA chip, or biochip) consists of a collection of microscopic DNA probes attached to a solid surface like glass, plastic, or silicon chips forming an array. These arrays are used to examine the profile expression of a gene, which is also known as the transcriptome or the set of messenger RNA (mRNA) transcripts expressed by a group of genes (Schulze and Downward, 2001).

To perform a microarray analysis, mRNA molecules are typically collected from both an experimental sample and a reference sample. The two mRNA samples are then converted into complementary DNA (cDNA), and each sample is labelled with a fluorescent probe of a different color. For instance, the experimental cDNA sample may be labelled with a red fluorescent dye, whereas the reference cDNA may be labelled with a green fluorescent dye. The two samples are then mixed together and allowed to bind to the microarray slide. The process in which the cDNA molecules bind to the DNA probes on the slide is called hybridization. Following hybridization, the microarray is scanned to measure the expression of each gene printed on the slide. If the expression of a particular gene is higher in the experimental sample than in the reference sample, then the corresponding spot on the microarray appears red. In contrast, if the expression in the experimental sample is lower than in the reference sample, then the spot appears green. Finally, if the expression are equal, then the spot appears yellow.

The measurement of gene expression by means of microarrays has a considerable interest both in the basic research field and in the medical diagnostics, in particular of genetic-based diseases, where the gene expression of healthy cells is compared with that of cells affected by the disease in question.

Other applications of microarrays are the analysis of SNPs (Single Nucleotide Polymorphisms), the comparison of RNA populations of different cells, and the use for new sequencing methods of the DNA.

There are different types of microarrays, catalogued depending on the material that is used as probes:

- cDNA microarray, with probes longer than 200 bases obtained for reverse transcription from mRNA, fragmented, amplified with PCR and deposited on a support glass or nylon;
- Oligonucleotide microarray, with probes with a length between 25 and 80 bases obtained from biological or artificial material and deposited on a glass support;
- Oligonucleotide microarray, with probes between 25 and 30 bases synthesized in situ with photolithographic techniques on silicon wafers.

For the analysis of gene expression two dominant technologies are present on the market: GeneChip, developed, marketed and patented by Affymetrix, Inc. and the “spotted” array, popularized by the Brown labs at Stanford.

Spotted Arrays

The first DNA micro-arrays used full length cDNA molecules (amplified using PCR) as probes. The probes were spotted onto glass slides with an activated surface capable of binding the DNA. The spotting process is the process of placing small droplets containing the cDNA probes in an organized grid on the micro-array slide. Spotted arrays can equally well be used with synthetic oligonucleotide probes.

Genechip

A completely different approach to the construction of DNA micro-arrays is to synthesize the probes directly on the surface of the array. The approach was initially commercialized by the company Affymetrix (California, USA) under the name “GeneChip”. The idea is to build the oligonucleotide one base at the time. Starting out with an empty activated silicon surface, the synthesis occurs during a series of coupling steps: in each step the four nucleotides are presented to the entire surface one at the time and will be coupled to the growing oligonucleotides in a tightly controlled manner. The individual positions on the array are targeted for coupling by a light-based deprotection of the oligonucleotides and the use of a series of lithographic masks to shield the rest of the array.

Next Generation Sequencing

Next generation technologies for DNA sequencing allow for high speed and throughput. The advantage of these technologies is the possibility of obtaining the DNA sequence by amplifying the fragment, without having to clone it (Metzker, 2010).

The Next Generation Sequencing (NGS) technology is based on the analysis of the light emitted from each nucleotide, which allows to identify the type. Unfortunately, the light that each of these emits is too small, thus, it must be amplified. To amplify it, PCR (polymerase chain reaction) is usually used. It is a technique that allows multiplication, and therefore amplification, of nucleic acid fragments of which the initial and final nucleotide sequences are known. After this stage, an amplified filament is obtained and it must be separated to be studied. Thus the second stage is the separation step. The separation can be performed using a picotiter plate (PTP), one specie of slide able to divide the various nucleotides. Once the nucleotides have been separated, it is possible to analyze them. The analysis is performed by detecting the light that each nucleotide emits, as the light emitted by each type of nucleotide is unique.

Commercial Systems for NGS

The main systems implementing the next generation sequencing techniques are described here (Buermans and den Dummen, 2014).

Roche 454 System. It was the first to be marketed in 2005. This system uses pyrosequencing and PCR amplification. Initially this system reached reads of 100–150 bp (bp means base pair), producing about 200,000 reads, with a throughput of 20 Mb per run.

In 2008 it was proposed an evolution, the GS4 GSX FLX Titanium sequencer, which reached 700 bp long reads, with an accuracy of 99.9% after filtering, with an output of 0.7 Gb per run in 24 h. In 2009, the combination of the GS Junior method with the 454 GS system led the output at 14 Gb per run. Further developments have led to the GS FLX +, able to sequence reads long up to 1 kb.

The high speed combined with the length of the reads produced, are the strong points of this system. However, the cost of the reagents remains a problem to be solved.

AB SOLiD System. was marketed by Applied Biosystems in 2006. The system uses the two-base sequencing method, based on the ligation sequencing, i.e., it performs filament analysis in both directions. Initially the length of the reads was only 35 bp, and

the output reached 3 Gb per run. Thanks to the two-base sequencing, the accuracy of the application reached 99.85% after filtering. In 2010 the SOLiD 5500x1 was released, with reads length of 85 bp, precision 99.99% and 30 Gb output per run. A complete run can be done in 7 days.

The main problem with this method is the length of the reads, which for many applications is not enough. The tool is used to sequence whole genomes, targeted sequences, epigenomic.

Illumina GA/HiSeq System. In 2006, Solexa released the genomic analyzer (GA), in 2007 the company was bought by Illumina. The system uses synthesis sequencing (SBS) and bridge amplification, an alternative at the PCR.

At first the output of the analyzer was 1 Gb per run, then brought to 50 Gb per run in 2009. In 2010 the HiSeq 2000 was released, which uses the same strategies as its predecessor, arriving for at 600 Gb per run, obtainable in 8 days. In the next future it should be able to even reach 1 Tb per run. Also the length of the reads has been improved, going from 35 bp to about 200 bp in the latest versions. The cost per operation is among the lowest, compared to the various sequencers.

Helicos single-molecule sequencing device (HeliScope) appeared for the first time in 2007. The method, unlike the previous ones, uses a technique that analyzes the molecules individually, this way it was possible to obtain even greater accuracy, not dirtying the genome with chemical reagents. Also for this system the throughput is in the order of Gigabases. However, the main disadvantage of this method remains the low capacitance to manage the indels (insertions-deletions) correctly, resulting in increased errors. Another problem is the length of the reads, which has never exceeded 50 bp.

Closing Remarks

High-throughput technologies allowed the development and proliferation of the 'omics' disciplines (i.e., genomics, proteomics, metabolic, transcriptomics, epigenomics, to cite a few). Moreover, they contribute to the generation of a high volume of data relative to different levels of biological complexity (DNA, mRNA, proteins, metabolites).

Standards and Models for Biological Data: Common Formats

Barbara Calabrese, University “Magna Graecia”, Catanzaro, Italy

© 2019 Elsevier Inc. All rights reserved.

Introduction

In bioinformatics and computational biology, the need to standardise the data is an important issue. Nowadays, there are many different ways of representing similar biological data and this makes the integration process and subsequent mining process more difficult.

Standards are defined as an agreed compliant term or structure to represent a biological activity (Lapatas *et al.*, 2015). The adoption of standards facilitates data re-use and sharing, allowing to overcome interoperability problems relative to different data formats. They provide uniformity and consistency in the data from different organizations and technologies. A standard within the omics data field, can be generally characterized by its domain and scope (Chervitz *et al.*, 2011). The domain refers to the type of experimental data (i.e., transcriptomics, proteomics, metabolomics), whereas the scope refers to the area of applicability of standard.

Standards for Biological Data

Numerous standard initiatives have been proposed, some of them are reported in the following paragraphs.

OBO, The Open Biological and Biomedical Ontologies: The Open Biological and Biomedical Ontology (OBO) Foundry (see “Relevant Websites section”) is a collective of ontology developers that are committed to collaboration and adherence to shared principles. The mission of the OBO Foundry is to develop a family of interoperable ontologies that are both logically well-formed and scientifically accurate. To achieve this, OBO Foundry participants voluntarily adhere to and contribute to the development of an evolving set of principles including open use, collaborative development, non-overlapping and strictly-scoped content, and common syntax and relations, based on ontology models that work well, such as the Gene Ontology (GO) (Smith *et al.*, 2007).

CDISC, Clinical data interchange standards consortium: The Clinical Data Interchange Standards Consortium (CDISC) (see “Relevant Websites section”) is a global, open, multidisciplinary, not-for-profit organization that has established standards to support the acquisition, exchange, submission and archive of clinical research data and metadata. The mission is to develop and support global, platform-independent data standards that enable information system interoperability to improve medical research and related areas of healthcare. CDISC standards are vendor-neutral and platform-independent freely available via the CDISC website (Huser *et al.*, 2015).

HUPO-PSI, Human Proteome Organization-Proteomics Standards Initiative: The Human Proteome Organization (HUPO) was formed in 2001 to consolidate national and regional proteome organizations into a single worldwide body (see “Relevant Websites section”). The Proteome Standards Initiative (PSI) was established by HUPO with the remit of standardizing data representation within the field of proteomics, to the end that public domain databases can be established where all such data can be deposited, exchanged, or downloaded and utilized by laboratory workers. The HUPO-PSI organized a series of meetings at which data producers, data users, instrumentation vendors, and analytical software producers, gathered to discuss the problem. As the HUPO-PSI is a completely voluntary organization with limited resources, activity is focussed on a few key areas of proteomics, constituting the PSI work groups.

GAGH, Global Alliance for Genomics and Health: The Global Alliance for Genomics and Health (GA4GH) is an international, nonprofit alliance formed in 2013 to accelerate the potential of research and medicine, to advance human health. Bringing together 500 + leading organizations working in healthcare, research, patient advocacy, life science, and information technology, the GA4GH community is working together to create frameworks and standards to enable the responsible, voluntary, and secure sharing of genomic and health-related data (see “Relevant Websites section”).

COMBINE, Computational Modeling in Biology: The ‘COMputational Modeling in Biology’ NETwork (COMBINE) is an initiative to coordinate the development of the various community standards and formats for computational models. By doing so, it is expected that the federated projects will develop a set of interoperable and non-overlapping standards covering all aspects of modeling in biology (see “Relevant Websites section”).

MSI, Metabolomics Standards Initiative: The Metabolomics Standards Initiative (MSI) was conceived in 2005, as an initiative of Metabolomics Society activities, now coordinated by the Data Standards Task Group of the Society. The MSI is an academic policy provider, to support the development of open data and metadata formats for metabolomics. MSI followed on earlier work by the Standard Metabolic Reporting Structure initiative (report) and the Architecture for Metabolomics consortium (ArMet). The early efforts of MSI were focused on community-agreed reporting standards, the so called minimal information (MI) checklists and data exchange formats to support the MIs reporting standards. MSI aim was to provide a clear description of the biological system studied and all components of a metabolomics study, as well as to allow data to be efficiently applied, shared and reused (see “Relevant Websites section”).

Clinical and Laboratory Standards Institute: The Clinical and Laboratory Standards Institute (see “Relevant Websites section”) is an international organization that develops and fosters clinical laboratory testing standards based on input from and consensus among industry, government, and health care professionals. The CLSI publishes standards for a wide range of biological specialties such as clinical chemistry and toxicology, hematology, method evaluation, microbiology, etc. It also provides guidance for obtaining accreditation and certifications as set by the International Organization for Standardization.

RDA, Research Data Alliance: The Research Data Alliance (RDA) was launched as a community-driven organization in 2013 by the European Commission, the United States Government's National Science Foundation and National Institute of Standards and Technology, and the Australian Government's Department of Innovation, with the goal of building the social and technical infrastructure to enable open sharing of data. With more than 6600 members from 135 countries (February 2018), RDA provides a neutral space where its members can come together through focused global Working and Interest Groups to develop and adopt infrastructure that promotes data-sharing and data-driven research, and accelerate the growth of a cohesive data community that integrates contributors across domain, research, national, geographical and generational boundaries (see "Relevant Websites section").

Formats for Biological Data

Biological data formats represent biological information in a file. High volume omics data cannot be manually analysed, thus there is the need of the adoption of commonly agreed formats to represent them in computer readable files.

Many different formats even to represent the same type of data have been proposed. However, as pointed out in the previous paragraphs, the adoption of standards in file formats is essential to data exchange and integration.

For example, in the case of NGS data, there are no standards, but a set of commonly used formats (FASTA/Q, SAM, VCF, GFF/GTF, etc.). This lack arises several issues relative to time and effort spent on converting raw files across multiple sequencing platforms to make these compatible (Lapatas *et al.*, 2015).

FASTA Format

FASTA format is a text-based format for representing either nucleotide sequences or amino acid sequences, in which base pairs or amino acids are represented using single-letter codes. Usually the first line starts with the ">" sign, followed by a sequence identification code, and optionally followed by a textual description of the sequence. Since it is not part of the official description of the format, software can choose to ignore this, when it is present. One or more lines contain the sequence itself. A file in FASTA format may comprise more than one sequence.

An example of a FASTA sequence (see "Relevant Websites section") is reported in the following:

BTBSCRYR

```

tgcaccaaacatgtctaaagctggaacccaaattactttcttgaagacaaaaactttca
aggccgccactatgacagcgattgcgactgtgcagattccacatgacctgagccgctg
caactccatcagatggaaggaggcacctgggctgtgtatgaaaggcccaatttgcctgg
gtacatgtacatcctacccggggcgagatcctgagtagcagcactggatgggcctcaa
cgaccgcctcagcctcctgcagggtgttcacctgtctagtggagccagataagcttca
gatctttgagaagggggttttaatggtcagatgcatgagaccaggaagactgcccttc
catcatggagcagttccacatgcgggaggtccactcctgttaagggtgctggaggcgctg
gatcttctatgagctgcccaactaccgaggcagggcagtagcctgtggacaagaaggagta
ccggaagcccgtcactgggtgcagcttcccagctgtccagcttccgcgcattgt
ggagtgtatcacagatgcggccaaacgctggctggcctgtcatccaataagcattat
aaataaacaattggcatgc

```

Sequences are expected to be represented in the standard IUB/IUPAC (see "Relevant Websites section") amino acid and nucleic acid codes.

The accepted nucleic acid codes are (see "Relevant Websites section"):

<i>IUPAC nucleotide code</i>	<i>Base</i>
A	Adenine
C	Cytosine
G	Guanine
T or U	Thymine or Uracil
R	A or G
Y	C or T
S	G or C
W	A or T
K	G or T
M	A or C
B	C or G or T
D	A or G or T
H	A or C or T
V	A or C or G
N	Any base
or -	gap

The accepted amino acid codes are (see “Relevant Websites section”):

<i>IUPAC amino acid code</i>	<i>Three letter code</i>	<i>Amino acid</i>
A	Ala	Alanine
C	Cys	Cysteine
D	Asp	Aspartic Acid
E	Glu	Glutamic Acid
F	Phe	Phenylalanine
G	Gly	Glycine
H	His	Histidine
I	Ile	Isoleucine
K	Lys	Lysine
L	Leu	Leucine
M	Met	Methionine
N	Asn	Asparagine
P	Pro	Proline
Q	Gln	Glutamine
R	Arg	Arginine
S	Ser	Serine
T	Thr	Threonine
V	Val	Valine
W	Trp	Tryptophan
Y	Tyr	Tyrosine

Gen-Bank Format

GenBank is the National Institutes of Health (NIH) genetic sequence database, an annotated collection of all publicly available DNA sequences (Benson *et al.*, 2013). GenBank is part of the International Nucleotide Sequence Database Collaboration (see “Relevant Websites section”), which comprises the DNA DataBank of Japan (DDBJ), the European Nucleotide Archive (ENA), and GenBank at NCBI.

GenBank format (GenBank Flat File Format) consists of an annotation section and a sequence section. An annotated sample GenBank record could be examined at the following link provided in: “Relevant Websites section”. The start of the annotation section is marked by a line beginning with the word “LOCUS”. The LOCUS field contains a number of different data elements, including locus name, sequence length, molecule type, GenBank division, and modification date. Furthermore, the annotation section contain the following main elements:

- **Definition:** It is a brief description of sequence; includes information such as source organism, gene name/protein name, or some description of the sequence’s function (if the sequence is non-coding). If the sequence has a coding region (CDS), description may be followed by a completeness qualifier, such as “complete cds”.
- **Accession:** It is the unique identifier for a sequence record.
- **Version:** A nucleotide sequence identification number that represents a single, specific sequence in the GenBank database.
- **GI:** “GenInfo Identifier” sequence identification number, in this case, for the nucleotide sequence. If a sequence changes in any way, a new GI number will be assigned.
- **Keywords:** Word or phrase describing the sequence. If no keywords are included in the entry, the field contains only a period.
- **Source:** Free-format information including an abbreviated form of the organism name, sometimes followed by a molecule type.
- **Organism:** The formal scientific name for the source organism (genus and species, where appropriate) and its lineage, based on the phylogenetic classification scheme used in the NCBI Taxonomy Database.
- **Reference:** Publications by the authors of the sequence that discuss the data reported in the record. References are automatically sorted within the record based on date of publication, showing the oldest references first.
- **Authors:** List of authors in the order in which they appear in the cited article.
- **Title:** Title of the published work or tentative title of an unpublished work.
- **Features:** Information about genes and gene products, as well as regions of biological significance reported in the sequence. These can include regions of the sequence that code for proteins and RNA molecules, as well as a number of other features.
- **Source:** Mandatory feature in each record that summarizes the length of the sequence, scientific name of the source organism, and Taxon ID number. Can also include other information such as map location, strain, clone, tissue type, etc., if provided by submitter.
- **Taxon:** A stable unique identification number for the taxon of the source organism.
- **CDS:** coding sequence; region of nucleotides that corresponds with the sequence of amino acids in a protein (location includes start and stop codons). The CDS feature includes an amino acid translation. Authors can specify the nature of the CDS by using the qualifier “/evidence=experimental” or “/evidence=not_experimental”.

- **protein_id:** A protein sequence identification number, similar to the Version number of a nucleotide sequence. Protein IDs consist of three letters followed by five digits, a dot, and a version number.
- **GI:** “GenInfo Identifier” sequence identification number, in this case, for the protein translation.
- **Translation:** The amino acid translation corresponding to the nucleotide coding sequence (CS). In many cases, the translations are conceptual. Note that authors can indicate whether the CDS is based on experimental or non-experimental evidence.
- **Gene:** a region of biological interest identified as a gene and for which a name has been assigned.

The start of sequence section is marked by a line beginning with the word “ORIGIN” and the end of the section is marked by a line with only “//”.

EMBL Format

The EMBL Nucleotide Sequence Database at the EMBL European Bioinformatics Institute, UK, offers a large and freely accessible collection of nucleotide sequences and accompanying annotation. The database is maintained in collaboration with DDBJ and GenBank (Kulikova *et al.*, 2007). The flatfile format used by the EMBL to represent database records for nucleotide and peptide sequences from EMBL database (Stoesser *et al.*, 2002). The EMBL flat file comprises of a series of strictly controlled line types presented in a tabular manner and consisting of four major blocks of data:

- **Descriptions and identifiers.**
- **Citations:** citation details of the associated publications and the name and contact details of the original submitter.
- **Features:** detailed source information, biological features comprised of feature locations, feature qualifiers, etc.
- **Sequence:** total sequence length, base composition (SQ) and sequence.

An example of EMBL flat file is reported in the following:

```
ID   XXX;   XXX;   {'linear' or 'circular'};   XXX;   XXX;   XXX;   XXX.

    [sequence truncated]...
```

SAM Format

SAM stands for Sequence Alignment/Map format. It is a TAB-delimited text format consisting of a header section, which is optional, and an alignment section. If present, the header must be prior to the alignments. Header lines start with ‘@’, while alignment lines do not. Each alignment line has 11 mandatory fields for essential alignment information such as mapping position, and variable number of optional fields for flexible or aligner specific information. In the following table, the mandatory fields are briefly described.

<i>No.</i>	<i>Name</i>	<i>Description</i>
1	QNAME	Query NAME of the read or the read pair
2	FLAG	Bitwise FLAG (pairing, strand, mate strand, etc.)
3	RNAME	Reference sequence NAME
4	POS	1-Based leftmost POSition of clipped alignment
5	MAPQ	MAPping Quality (Phred-scaled)
6	CIGAR	Extended CIGAR string (operations: MIDNSHP)
7	MRNM	Mate Reference NaMe ('=' if same as RNAME)
8	MPOS	1-Based leftmost Mate POSition
9	ISIZE	Inferred Insert SIZE
10	SEQ	Query SEquence on the same strand as the reference
11	QUAL	Query QUALity (ASCII-33 = Phred base quality)

They must be present but their value can be a '*' or a zero (depending on the field) if the corresponding information is unavailable. The optional fields are presented as key-value pairs in the format of TAG:TYPE:VALUE. They store extra information from the platform or aligner. The SAM format specification gives a detailed description of each field and the predefined TAGs (Li *et al.*, 2009).

VCF Format

The variant call format (VCF) is a generic format for storing DNA polymorphism data such as SNPs, insertions, deletions and structural variants, together with rich annotations (Danecek *et al.*, 2011). VCF is usually stored in a compressed manner and can be indexed for fast data retrieval of variants from a range of positions on the reference genome. The format was developed for the 1000 Genomes Project, but it has also been adopted by other projects. A VCF file consists of a header section and a data section. The header contains an arbitrary number of meta-information lines, each starting with characters '##', and a TAB delimited field definition line, starting with a single '#' character. The meta-information header lines provide a standardized description of tags and annotations used in the data section. It can be also used to provide information about the means of file creation, date of creation, version of the reference sequence, software used and any other information relevant to the history of the file. The field definition line names eight mandatory columns, corresponding to data columns representing the chromosome (CHROM), a 1-based position of the start of the variant (POS), unique identifiers of the variant (ID), the reference allele (REF), a comma separated list of alternate non-reference alleles (ALT), a phred-scaled quality score (QUAL), site filtering information (FILTER) and a semicolon separated list of additional, user extensible annotation (INFO). In addition, if samples are present in the file, the mandatory header columns are followed by a FORMAT column and an arbitrary number of sample IDs that define the samples included in the VCF file. The FORMAT column is used to define the information contained within each subsequent genotype column, which consists of a colon separated list of fields. All data lines are TAB delimited and the number of fields in each data line must match the number of fields in the header line.

The VCF specification includes several common keywords with standardized meaning. In the following some examples of the reserved tags:

Genotype columns:

- GT, genotype, encodes alleles as numbers: 0 for the reference allele, 1 for the first allele listed in ALT column, 2 for the second allele listed in ALT and so on. The number of alleles suggests ploidy of the sample and the separator indicates whether the alleles are phased ('/') or unphased ('/') with respect to other data lines.
- PS, phase set, indicates that the alleles of genotypes with the same PS value are listed in the same order.
- DP, read depth at this position.
- GL, genotype likelihoods for all possible genotypes given the set of alleles defined in the REF and ALT fields.
- GQ, genotype quality, probability that the genotype call is wrong under the condition that the site is being variant. Note that the QUAL column gives an overall quality score for the assertion made in ALT that the site is variant or no variant.

INFO column: Missing values are represented with a dot. For practical reasons, the VCF specification requires that the data lines appear in their chromosomal order. The full format specification is available at the VCFtools web site.

- DB, dbSNP membership.
- H3, membership in HapMap3.
- VALIDATED, validated by follow-up experiment.
- AN, total number of alleles in called genotypes.
- AC, allele count in genotypes, for each ALT allele, in the same order as listed.
- SVTYPE, type of structural variant (DEL for deletion, DUP for duplication, INV for inversion, etc. as described in the specification).
- END, end position of the variant.
- IMPRECISE, indicates that the position of the variant is not known accurately; and

- CIPOS/CIEND, confidence interval around POS and END positions for imprecise variants.

Other common biological data formats

Despite the large variety of computer readable formats, Lapatas *et al.* realised that the most commonly used ones are ascribable to four main different classes (Lapatas *et al.*, 2015):

- *Tables*: In table formats, data are organized in a table in which the columns are separated by tabs, commas, pipes, etc., depending on the source generating the file.
- *FASTA-like*: FASTA-like files utilise, for each data record, one or more “definition” or “declaration lines”, which contain metadata information or specify the content of the following lines. Definition/declaration lines usually start with a special character or keyword in the first position of the line – a “>” in FASTA files or a “@” in fastq or SAM files – followed by lines containing the data themselves. In some cases, declaration lines may be interspersed with data lines. This format is mostly used for sequence data.
- *GenBank-like*: In the GenBank-like format, each line starts with an identifier that specifies the content of the line.
- *tag-structured*: Tag-structured formatting uses “tags” “(“,”)”, “{“, “}”, etc. to make data and metadata recognisable with high specificity. Tag-structured text files, especially XML and JSON, are being increasingly employed as data interchange formats between different programming languages.

There are also examples of data files using different representations for data and metadata. This means that two or more format classes may be used in the same data file. Some authors propose to adopt XML for biological data interchange between databases.

Concluding Remarks

Standards adoption facilitates data integration and sharing of omics data. They improve interoperability by overcoming problems relative to different data formats, architectures, and naming conventions. The definition and usage of standards increases productivity and fosters availability of a major volume of data to researchers.

Introduction

The increase in the rate and amount of data currently being generated thanks to new high-throughput sequencing (HTS) technologies poses challenges in the data collection, management and sharing. Specifically, HTS is used not only for traditional applications in genomics, but also to assay gene expression (RNA-seq), transcription factor binding, DNA methylation. Availability of the data generated through HTS technologies in usable formats is essential not only for peer-review process and to guarantee experimental reproducibility, but also to allow integration of multiple experiments across multiple modalities (Brazma *et al.*, 2001).

Within the field of proteomics, mass spectrometry (MS) delivers ever-faster cycle times with high sensitivity and high quality MS spectra. Improved separation techniques have increased the rate at which samples can be fed into these machines and protein identification algorithms can rapidly search high quality protein sequence databases, and assign an ever-increasing proportion of spectra as being generated from a specific protein fragment. All such data is of value to the researcher and needs to be made accessible in an easily accessible form. Once validated, the data is then available to act as a reference set against which other experimental results can be compared. In order to do this, the original data needs to be stored in a format appropriate for the researcher to access, download and analyse.

This paper aims to examine the major standard initiatives in genomics and proteomics fields.

FGED

The Functional Genomics Data (FGED) Society, was founded in 1999 as the MGED (Microarray and Gene Expression Data) Society because its original focus is on microarrays and gene expression data. In July 2010, the society changed its name to the “Functional Genomics Data (FGED) Society” to reflect its current mission which goes beyond microarrays and gene expression to encompass data generated using any functional genomics technology applied to genomic-scale studies of gene expression, binding, modification (such as DNA methylation), and other related applications.

They work with other organizations to accelerate and support the effective sharing and reproducibility of functional genomics data. They facilitate the creation and use of standards and software tools that allow researchers to annotate and share their data easily. Finally, they promote scientific discovery that is driven by genome wide and other biological research data integration and meta-analysis.

The major standardization projects being pursued by the FGED Society include:

- MIAME – The formulation of the minimum information about a microarray experiment required to interpret and verify the results.
- MINSEQE – The development of the Minimum Information about a high-throughput SEQuencing Experiment standard for Ultra High-Throughput Sequencing experiments.
- MAGE-TAB – A simple spreadsheet-based, MIAME-supportive format for microarray experimental data called MAGE-TAB, based on a richer data exchange and object modelling format known as MAGE.
- Annotare – A stand-alone desktop application to help bench biologists annotate biomedical investigations and their resulting data.
- Ontology – The development of ontologies for microarray experiment description and biological material (biomaterial) annotation in particular.
- Collaborative standards – Engaging with and supporting the efforts of other relevant standards organizations, such as MIBBI (Minimum Information for Biological and Biomedical Investigations) (Taylor, 2008), ISA-TAB (Investigator/Study/Assay Infrastructure, see “Relevant Websites section”) (Sansone, 2012), OBI (Ontology for Biomedical Investigations, see “Relevant Websites section”).

MIAME

MIAME describes the Minimum Information About a Microarray Experiment that is needed to enable the interpretation of the results of the experiment unambiguously and potentially to reproduce the experiment (Brazma *et al.*, 2001).

The six most critical elements contributing towards MIAME are:

- The raw data for each hybridisation (e.g., CEL or GPR files).
- The final processed (normalised) data for the set of hybridisations in the experiment (study) (e.g., the gene expression data matrix used to draw the conclusions from the study).

- The essential sample annotation including experimental factors and their values (e.g., compound and dose in a dose response experiment).
- The experimental design including sample data relationships (e.g., which raw data file relates to which sample, which hybridisations are technical replicates, which are biological replicates).
- Sufficient annotation of the array (e.g., gene identifiers, genomic coordinates, probe oligonucleotide sequences or reference commercial array catalog number).
- The essential laboratory and data processing protocols (e.g., what normalisation method has been used to obtain the final processed data).

MINSEQE

MINSEQE describes the Minimum Information about a high-throughput nucleotide SEQuencing Experiment, that is needed to enable the unambiguous interpretation and facilitate reproduction of the results of the experiment (MINSEQE, 2012). By analogy to the MIAME guidelines for microarray experiments, adherence to the MINSEQE guidelines will improve integration of multiple experiments across different modalities, thereby maximising the value of high-throughput research.

The five elements of experimental description considered essential when making data available supporting published high-throughput sequencing experiments are as follows:

- The description of the biological system, samples, and the experimental variables being studied: “compound” and “dose” in dose-response experiments or “antibody” in ChIP-Seq experiments, the organism, tissue, and the treatment(s) applied.
- The sequence read data for each assay: read sequences and base-level quality scores for each assay; FASTQ format is recommended, with a description of the scale used for quality scores.
- The ‘final’ processed (or summary) data for the set of assays in the study: the data on which the conclusions in the related publication are based, and descriptions of the data format. Currently there are no widely adopted formats for processed HTS data, thus the descriptions of the data format should be provided. For gene expression, in many cases, these data can be presented as a matrix, with each row corresponding to a genomic region (such as an gene), each column representing a particular biological state (e.g., a time point in a time b course experiment), and each element in the matrix representing a measurement of the particular genomic region in the particular biological state. Similarly, other applications like ChIP=Seq analyses typically generate tabular output.
- General information about the experiment and sample-data relationships: a summary of the experiment and its goals, contact information, any associated publication, and a table specifying sample-data relationships.
- Essential experimental and data processing protocols: how the nucleic acid samples were isolated, purified and processed prior to sequencing, a summary of the instrumentation used, library preparation strategy, labelling and amplification methodologies. Moreover, data processing and analysis protocols must be described in sufficient detail to enable unambiguous data interpretation and to enable scientists to reproduce the analysis steps. This should include, but is not limited to, data rejection methods, data correction methods, alignment methods, data smoothing and filtering methods and identifiers used for reference genomes to which the sequences were mapped.

MAGE-TAB

The MAGE project aims to provide a standard for the representation of microarray expression data that would facilitate the exchange of microarray information between different data systems. Sharing of microarray data within the research community has been greatly facilitated by the development of the MIAME and MAGE-ML (Microarray and Gene Expression Markup Language) standards by the FGED Society. However, the complexity of the MAGE-ML format has made its use impractical for laboratories lacking dedicated bioinformatics support. MAGE-TAB is a simple tab-delimited, spreadsheet-based format, which will become a part of the MAGE microarray data standard and can be used for annotating and communicating microarray data in a MIAME compliant fashion. MAGE-TAB enables laboratories without bioinformatics experience or support to manage, exchange and submit well-annotated microarray data in a standard format using a spreadsheet. The MAGE-TAB format is self-contained, and does not require an understanding of MAGE-ML or XML.

MGED Ontology and Ontology for Biomedical Investigations

The purpose of the MGED ontology was to provide, either directly or indirectly, the terms needed to follow the MIAME guidelines and referenced by MAGE. The MGED ontology was an ontology of experiments, specifically microarray experiments, but it was potentially extensible to other types of functional genomics experiments. Although the major component of the ontology involved biological descriptions, it was not an ontology of molecular, cellular or organismal biology. Rather, it was an ontology that included concepts of biological features relevant to the interpretation and analysis of an experiment (Stoeckert and Parkinson, 2003).

The original MGED Ontology (MO) is being incorporated into the Ontology for Biomedical Investigations (OBI). The Ontology for Biomedical Investigations (OBI, see “Relevant Websites section”) is build in a collaborative, international effort and will serve as a resource for annotating biomedical investigations, including the study design, protocols and instrumentation used,

the data generated and the types of analysis performed on the data. This ontology arose from the Functional Genomics Investigation Ontology (FuGO) and will contain both terms that are common to all biomedical investigations, including functional genomics investigations and those that are more domain specific (Bandrowski *et al.*, 2016).

ANNOTARE

Annotare (see “Relevant Websites section”) is a tool to help biologists annotate biomedical investigations and their resulting data. Annotare is a stand-alone desktop application that features the following:

- A set of intuitive editor forms to create and modify annotations,
- Support for easy incorporation of terms from biomedical ontologies,
- Standard templates for common experiment types,
- A design wizard to help create a new document, and
- A validator that checks for syntactic and semantic violation.

Annotare will help a biologist construct a MIAPE-compliant annotation file based on the MAGE-TAB format.

HUPO

The Human Proteome Organisation (HUPO) was formed in 2001 to consolidate national and regional proteome organizations into a single worldwide body. The Proteome Standards Initiative (PSI) was established by HUPO with the aim of standardizing data representation within the field of proteomics to the end that public domain databases can be established where all such data can be deposited, exchanged between such databases or downloaded and utilized by laboratory workers.

The HUPO-PSI organized a series of meetings at which data producers, data users, instrumentation vendors and analytical software producers gathered to discuss the problem. As the HUPO-PSI is a completely voluntary organisation with limited resources, activity is focused on a few key areas of proteomics, constituting the PSI work groups. Currently, there are the following work groups (Orchard and Henjakob, 2007):

- Molecular Interactions (MI): The Molecular Interactions working group is concentrating on: (i) improving the annotation and representation of molecular interaction data wherever it is published, e.g., in journal articles, authors web-sites or public domain databases (Orchard *et al.*, 2011, 2007, 2012; Bourbeillon *et al.*, 2010) and (ii) improving the accessibility of molecular interaction data to the user community by presenting it in a common standard data format (PSI-MI XML (Proteomics Standards Initiative-Molecular Interactions/MITAB (Molecular Interaction TAB, a tab-delimited data exchange format, developed by the HUPO Proteomics Standards Initiative). Thus, the data can be downloaded from multiple sources and easily combined using a single parser.
- Mass Spectrometry (MS): The PSI-MS working group defines community data formats and controlled vocabulary terms facilitating data exchange and archiving in the field of proteomics mass spectrometry (Mayer *et al.*, 2013, 2014).
- Proteomics Informatics (PI): The main current deliverable of the Proteomics Informatics working group is the mzIdentML data exchange standard (previously known as analysis XML).
- Protein Modifications (PSI-MOD): The protein modification workgroup focuses on developing a nomenclature and providing an ontology available in OBO format or in OBO.xml (Montecchi Palazzi *et al.*, 2008).
- Protein Separation (PS): The PSI Protein Separation work group is a collaboration of researchers from academia, industrial partners and software vendors. The group aims to develop reporting requirements that supplement the MIAPE parent document, describing the minimum information that should be reported about gel-based (Gibson *et al.*, 2008; Hoogland *et al.*, 2010), and non-gel based separation technologies (Domann *et al.*, 2010; Jones *et al.*, 2010) employed for proteins and peptides in proteomics. The group will also develop data formats for capturing MIAPE-compliant data about these technologies (Gibson *et al.*, 2010) and supporting controlled vocabularies.

The standard deliverables of each work group are:

- Minimum Information Specification: for the given domain, this specifies the minimum information required for the useful reporting of experimental results in this domain.
- Formal exchange format for sharing experimental results in the domain. This will usually be an XML format, capable of representing at least the Minimum Information, and normally significant additional detail.
- Controlled vocabularies.
- Support for implementation of the standard in publicly available tools.

PSI-MI XML

It is a community data exchange format for molecular interactions which has been jointly developed by major data providers from both academia and industry. This format is based on XML and is stable and used for several years (Kerrien, 2007). It can be used for storing any kind of molecular interactions data:

- Complexes and binary interactions;
- Not only protein-protein interactions, but also nucleic acids interactions and others;
- Hierarchical complexes hierarchical complexes modelling by using interaction Ref in participants instead of an interactor.

Data representation in PSI-MI 2.5 XML relies heavily on the use of controlled vocabularies in OBO format. These vocabularies are essential for standardizing not only the syntax, but also the semantics of the molecular interactions representation. PSI-MI 2.5 standard defines also a simple tabular representation (MITAB).

Two different flavours of this format have been developed: the **Compact** format and the **Expanded** format. In the Compact format, the description of experiments and interactors is done at the beginning of the **entry** using **experimentList** and **interactorList** elements. When describing the interactions (in the next element **interactionList**), we will use references to the previously described experiments and interactors using their **id** attributes.

In the Expanded format, the description of experiments and interactors is done within each interaction. The file doesn't contain any **experimentList** or **interactorList** at the **entry** level, it only contains an **interactionList** (see "Relevant Websites section").

mzML

mzML is the PSI standard file format for mass spectrometry output files (Martens *et al.*, 2011). The full technical details of the mzML standard are available online, together with complete specification documentation, graphical depictions of its structure, and various example files at "see Relevant Websites section". All of the information from a single MS run, including the spectra and associated metadata, is contained within the mzML file. mzML is encoded in XML. An XML schema definition defines the format structure, and many industry-standard tools are readily available to validate whether an XML document conforms to its XML schema definition.

The overall mzML file structure is as follows (elements presented top-to-bottom): **<cvList>** contains information about the controlled vocabularies referenced in the rest of the mzML document; **<fileDescription>** contains basic information on the type of spectra contained in the file; **<referenceableParamGroupList>** is an optional element that of groups of controlled vocabulary terms that can be referenced as a unit throughout defines a list the document; **<sampleList>** can contain information about samples that are referenced in the file; **<instrumentConfigurationList>** contains information about the instrument that generated the run; **<softwareList>** and **<dataProcessingList>** provide a history of data processing that occurred after the raw acquisition; **<acquisitionSettingsList>** is an optional element that stores special input parameters for the mass spectrometer, such as inclusion lists. These elements are followed by the acquired spectra and chromatograms. Both spectral and chromatographic data are represented by binary format data encoded into base 64 strings, rather than human-readable ASCII text for enhanced fidelity and efficiency when dealing with profile data.

Mzidentml

The Proteomics Informatic working group is developing standards for describing the results of identification and quantification processes for proteins, peptides and protein modifications from mass spectrometry. mzIdentML is an exchange standard for peptide and protein identification data. The mzIdentML standard is, similar to mzML. The mzIdentML format stores peptide and protein identifications based on mass spectrometry and captures metadata about methods, parameters, and quality metrics. Data are represented through a collection of protein sequences, peptide sequences (with modifications), and structures for capturing the scores associated with ranked peptide matches for each spectrum searched.

Concluding Remarks

Omics technologies represent a fundamental tool for discovery and analysis in the life sciences. With the rapid advances, it has become imperative to provide a standard output format for data that will facilitate data sharing and analysis. To resolve the issues associated with having multiple formats, vendors, researchers, and software developers established standard initiatives, such as FGED or HUPO PSI to develop a single standard. They propose new data formats for genomic and proteomics data, adding a number of improvements, including features such as a controlled vocabulary and/or ontologies with validation tools to ensure consistent usage of the format and immediately available implementations to facilitate rapid adoption by the community.

Standards and Models for Biological Data: SBML

Giuseppe Agapito, University “Magna Graecia” of Catanzaro, Catanzaro, Italy

© 2019 Elsevier Inc. All rights reserved.

Introduction

Life science involves the scientific study of living organisms. Understanding how living organisms work is one of the greatest challenges that researchers are facing. Understanding how an organism work is challenging since it is necessary to identify all the interactions that happen inside the cells. Numerous experimental techniques (Abu-Jamous *et al.*, 2015) have been proposed such as, Polymerase Chain Reaction (PCR), Western Bolt, microarrays, Next Generation Sequencing (NGS) that have made possible to identify the components (known as biomolecules) inside the cell and how interacting to regulate the proper functioning of an organism. As well as the interactions between large molecules DNA, RNA, proteins and small molecules sugars, lipids, hormones, and vitamins. An in-depth knowledge of how these biomolecules interact among them is mandatory in order to understand how the cellular machinery works and the cellular processes are regulated. To develop a simple and efficient formalism able to convey how a cell work, how cellular processes are regulated and how the cell responds to internal and external stimuli, is mandatory. Thus, the interactions among the different types of molecules inside and outside the structure of the cell that regulate its functioning can be represented by means of networks. In particular, the variety of interactions between genes, proteins, and metabolites are well caught by network representations. In the simplest approximation, large and small biomolecules can be represented as nodes in a network whose edges represent various types of interaction between the nodes. This has given rise to the concept of system biology, which pursues the objective to provide the tools and the formalisms necessary to understand how the single biomolecules interact and evolve. The field of systems biology encompasses scientists with extremely various backgrounds comprising biologists, biochemists, clinicians, physiologists, mathematicians, physicists, computer scientists, and engineers. This has made it possible to realise models able to reproduce the behavior of a cell or even of a whole organism (Faro *et al.*, 2011; Eschrich *et al.*, 2009). Such models can speed up the investigation of the physiological mechanisms at the base of human diseases as well as improve the development and testing of new and more efficient drugs. To achieve this goal, it is essential that researchers can exchange data at their disposal, as this would allow for quicker explanations to complex illnesses such as cancer. Although data exchange would seem a very simple step to accomplish, it is not so immediate because of the absence of a single format for the representation of the biological system. This abundance of formats used to represent biological systems has lead to numerous problems, for example, (i) Researchers often need to use several different tools to make it possible to integrate data coming from different databases, or even worst manually re-encode data to be further analyzed, a time-consuming and error-prone process; (ii) Manually data manipulation made data stranded and unusable. Resulting in loss of re-usability, especially after data manipulation that makes data not more compatible with the original database. The current inability to exchange biological systems data models could be overcome by using a standard format for describing system biological models. To address those issues, it is necessary to develop a universal standard able to represent and exchange system biological models. In particular, to model ordinary differential equations (ODE) the standard language Systems Biology Markup Language (SBML) (Hucka *et al.*, 2003) has been proposed for efficient exchanging, storing and modeling of system biological models.

SBML is a computer-readable XML-based language for representing and exchanging models in a unique and universal format. The eXtensible Markup Language – XML (Bray *et al.*, 1997) is a markup language designed to be self-descriptive. XML stores data in plain text format, providing software and hardware independent method to store, transport, and share data. Due to this features, XML became like a standard data language even for bioinformatics. The adoption of SBML to store, exchange, and share data, would help to solve the problems of interoperability. In this way, users would be better capable of spending more time on research task rather than on struggling with data format issues.

Systems Biology Markup Language

SBML is a machine-readable format to represent biological models. In particular, SBML is focused on describing systems where biological entities are involved in, and modified by the processes that occur over time. An example of this is a biological network. SBML can represent models including cell signaling pathways, metabolic pathways, biochemical reactions, gene regulation, and many others. SBML allow describing biological models into a formal and computable format that can be analyzed rigorously by using scientific methods. As well as, SBML allow to represent models in several different representations related to its own biological scenarios. The primary target of SBML is to provide a standard format able to allow system biological data exchanging, storing and reusability. SBML is not a universal language for representing biological models. It would be impossible to produce a one-size-fits-all universal language for the biological systems. The use of SBML simplifies the sharing and analyzing of models among of multiple tools, without that users have to worry about to make it compatible with each software tool. SBML is independent of the programming languages and software tools, enabling the encoding of the biological models by means of XML.

By supporting SBML for reading and writing models, software tools can straightforwardly share, elaborate and store the biological models, as well as enabling the sharing among scientists of the outcomes obtained from well-defined models. Allowing to improve and speed-up the understanding of complex biological phenomena. SBML is a modular language, consisting of a comprehensive core that can be used alone. The most recent specification of SBML is SBML Level 3. The modular core of SBML allows adding new features in an easy way. SBML Levels are intended to coexist, that is SBML Level 3 does not make Level 2 obsolete, i.e., all models that have been writing by using SBML Level 2 are compatible with all software tools still continue to be used.

SBML Structure

SBML's markups define a set of rules for encoding biological models that are human and machine readable. A model definition in SBML Levels 3 Version 1 comprises a list of the following elements.

- Function definition: a mathematical function that could be used to describe the biological model;
- Unit definition: units can be used in the expression of quantities in a model where species may be located.
- Compartment: a container of limited dimensions where species may be placed. Compartments may or not describe real physical structures.
- Unit definition: a named definition of a new unit of measurement. Named units can be used in the expression of quantities in a model.
- Species: a set of entities of the same kind located in a compartment and participating in reactions process. SBML can represent any entity that makes sense in the context of a given model.
- Parameter: in SBML, the term parameter is used to indicate constants and or variables into a model. Moreover, SBML Level 3 provides the ability to define global parameters for a model as well as local parameters to a single process.
- Initial assignment: used to determine the initial conditions of a model by means of mathematical expressions. This value is used to define the value of a variable at the start of simulated time.
- Rule: mathematical expressions used to define how a variable's value can be calculated from other variables. Making possible to infer the behavior of the model with respect to time.
- Constraint: a means of detecting out-of-bounds conditions during a dynamical simulation and are defined by a general mathematical expression.
- Reaction: a statement describing transformation, transport or binding process that can change the amount of one or more elements.
- Event: a statement describing changes in one or more variables of any type (species, compartment, parameter, etc.) when a condition is satisfied.

    .....

```

Code 2.1: This is a part of the genome-scale *E. coli* reconstruction and contains central metabolism reactions, encoded by using the SBML Level 2 format.

SBML Packages

SBML Level 3 has been designed in a modular fashion. This makes it possible to use the core specification independently or to add extra packages onto the core to provide further features.

- **Hierarchical Model Composition:** the Hierarchical Model Composition package provides the ability to combine models as submodels inside another model. A feature that makes it possible to decompose larger models into smaller ones, to avoid duplication of elements; and finally create reusable libraries.
- **Flux Balance Constraints:** the Flux Balance Constraints package provides support to analyze and study biological networks.
- **Qualitative Models:** the Qualitative Models package provide the tools to represent models partially that is, biochemical reactions and their kinetics are not entirely known.
- **Layout:** the SBML layout package contains the guidelines to represent a reaction network in a graphical form. SBML layout package only deals with the information necessary to define the position and other aspects of a graph's layout; the additional details regarding the rendering, are provided in a separate package called Rendering package.

SBML Specification Differences

SBML is defined in a set of Requirement documents describing the elements of the language, the syntax, and validation rules. SBML Levels are intended to coexist. Thus SBML Level 3 does not render Level 2 and Level 1 obsolete. As a good rule for each Level, the latest Version should be used. SBML is an active project under continuous updating and developed in collaboration with an international community of researchers and software developers.

SBML Level 1 Version 2

Systems Biology Markup Language (SBML) Level 1, Version 2 is a description language for simulations in systems biology. The goals pursuit by SBML are, allow to users to represent biochemical networks, including cell signaling pathways, metabolic pathways, biochemical reactions, and many others. SBML has been developed has an XML-based format for coding systems

biology models in a simple format that software tools can manage and exchange. However, for easier communication to human readers, there is a visual version of SBML developed upon the Unified Modeling Language graphical language (UML) the (Eriksson and Penker, 1998). UML-based definition is necessary to define the XML Schema (Biron and Malhotra, 2000) for SBML. The top-level components of the SBML Level 1, Version 2 model are the following:

- Unit definition: a name for a unit used in the expression of quantities in a model.
- Compartment: a container of finite volume for substances. In SBML Level 1, a compartment is primarily a topological structure with a size but no geometric qualities.
- Species: a substance or entity that takes part in a reaction. Some example species are ions such as and molecule such as glucose or ATP.
- Reaction: a statement describing transformation, transport or binding process that can change the amount of one or more elements.
- Parameter: in SBML, the term parameter is used to indicate constants and or variables into a model. Moreover, SBML Level 3 provides the ability to define global parameters for a model as well as local parameters to a single process.
- Rule: in SBML, a mathematical expression that is added to the differential equations constructed from the set of reactions and can be used to set parameter values, establish constraints between quantities, etc.

A software framework can read a model conveyed in SBML and translate it into its own internal format for model analysis. For instance, a framework might provide the tools to simulate a model by means of a set of differential equations representing the network, to perform a numerical integration to investigate the model's dynamic behavior. SBML allows representing models of arbitrary complexity. Each component type present in a model is described through a particular data structure type, able to organize the important information. The data structures determine how the resulting model is encoded in XML. To get more information on the items introduced before, it is advised to consult the specification reported at the following address: <http://co.mbine.org/specifications/sbml.level-1.version-2.pdf>.

SBML Level 2 Version 5 Release 1

The Systems Biology Markup Language (SBML) Level 2 Version 5 Release 1 is a model representation format for systems biology. The main intend of SBML Level 2 Version 5 Release 1 is to provide a formal language to represent biochemical networks. Also, SBML project is not an attempt to define a universal language for representing biological system models. SBML Level 2 Version 5 Release 1 allows to describe models of arbitrary complexity. Each type of component in a model is described using a particular type of data object that organizes the relevant information. The head level of an SBML model definition consists of lists of these components, with every list being optional, the meaning of each component is as follows:

- Function definition: a named mathematical function that may be used throughout the rest of a model.
- Unit definition: a named definition of a new unit of measurement, or a redefinition of an SBML predefined unit.
- Compartment type: a type of location where reacting entities such as chemical substances may be located.
- Species type: a type of entity that can participate in reactions. Typical examples of species types include ions such as Ca²⁺, molecules such as glucose or ATP, and more.
- Compartment: a container of finite volume for substances. In SBML Level 1, a compartment is primarily a topological structure with a size but no geometric qualities.
- Species: a pool of entities of the same species type located in a particular compartment.
- Parameter: in SBML, the term parameter is used to indicate constants and or variables into a model. Moreover, SBML Level 3 provides the ability to define global parameters for a model as well as local parameters to a single process.
- Initial assignment: used to determine the initial conditions of a model by means of mathematical expressions. This value is used to define the value of a variable at the start of simulated time.
- Rule: mathematical expressions used to define how a variable's value can be calculated from other variables. Making possible to infer the behavior of the model with respect to time.
- Event: a statement describing changes in one or more variables of any type (species, compartment, parameter, etc.) when a condition is satisfied.
- Constraint: a means of detecting out-of-bounds conditions during a dynamical simulation and are defined by a general mathematical expression.
- Reaction: a statement describing transformation, transport or binding process that can change the amount of one or more elements.

To get more detailed information on the items introduced before, it is advised to consult the specification reported are the following address: <http://co.mbine.org/specifications/sbml.level-2.version-5.release-1.pdf>.

SBML Level 3 Version 1 core release 2

Major editions of SBML are termed levels and represent substantial changes to the composition and structure of the language. The SBML Level 3 Version 1 core release 2 (Hucka *et al.*, 2010, 2015), represents an evolution of the first version of the language.

SBML Level 3 Version 1 core release 2 allows models of arbitrary complexity to be represented. Each type of component in a model is described using a particular type of data object that organizes the relevant information. The top level of an SBML model

definition consists of lists of these components, with every list being optional, the meaning of each component is as follows: The top level of an SBML model definition consists of lists of these components, with every list being optional, the meaning of each component is as follows:

- Function definition: a named mathematical function that may be used throughout the rest of a model.
- Unit definition: a named definition of a new unit of measurement. Named units can be used in the expression of quantities in a model.
- Compartment: a well-stirred container of a finite size where species may be located. Compartments may or may not represent actual physical structures.
- Species: a pool of entities of the same species type located in a particular compartment.
- Parameter: in SBML, the term parameter is used to indicate constants and or variables into a model. Moreover, SBML Level 3 provides the ability to define global parameters for a model as well as local parameters to a single process.
- Initial assignment: used to determine the initial conditions of a model by means of mathematical expressions. This value is used to define the value of a variable at the start of simulated time.
- Rule: mathematical expressions used to define how a variable's value can be calculated from other variables. Making possible to infer the behavior of the model with respect to time.
- Constraint: a means of detecting out-of-bounds conditions during a dynamical simulation and are defined by a general mathematical expression.
- Reaction: a statement describing transformation, transport or binding process that can change the amount of one or more elements.
- Event: a statement describing an immediate, discontinuous change in one or more symbols of any type (species, compartment, parameter, etc.) when a condition is satisfied.

To get more detailed information on the items introduced before, it is advised to consult the specification reported are the following address: <http://co.mbine.org/specifications/sbml.level-3.version-1.core.release-2>.

In brief, the main differences between the 3 versions of SBML are the number of available components. Compared to version 1 in subsequent releases, components have increased, making it possible to describe a larger number of biological systems. Also, from the version two, all the elements are optional, making it easier to explain phenomena in a partial way. From version 2 to version 3, the compartment types and species types have been removed, since in version 3 the compartment component can contain several different entities, thus rendering obsolete the use of components types and species types.

Introduction

With the continuous evolution of biotechnologies, the study of biological systems is moving toward a molecular level. This changing is due to the capabilities of the new technologies to capture a significant amount of information on molecular changes associated with the particular condition of biological systems. Although the evolution of innovative technologies has made it possible to the sequencing of the whole human genome, the analysis of the vast amount of data available from the sequencing of the genome presents several difficulties. These difficulties are related with the intricate networks of interactions that regulate how a cell works, how cellular processes are regulated and how the cell responds to internal and external stimuli. Making difficult (often impossible), to map genome or proteome data together to obtain a clear vision of how to work an organism or a single cell. Thus, became essential to detect, store and model the interactions network among the different types of molecules inside and outside the structure of the cell. These interactions information known as biological pathways, are available in several internet public accessible databases. Researchers frequently need to exchange, integrate these information to improve their research activities, but the high heterogeneity among all this data source contribute to making difficult to retrieve, integrate and store data from multiple databases. To reach the target, it is crucial that researchers can easily exchange their data, making data collection and integration easier. This heterogeneity of formats used to represent biological pathways has to lead to several complications, for example, researchers have to use several different tools to integrate data coming from different databases. Even worst researchers manually have to re-encode data to be further analyzed, a time-consuming and error-prone process. All these issues, limiting the usability of the data, especially after manipulation, making data not more compatible with the original databases. The current inability to exchange, integrate and annotate biological pathways data models could be overcome by using a unique standard format for biological pathways. The Biological Pathway Exchange (BioPAX, see Relevant Website section) is an OWL-based data format that enables the integration of different pathway data by defining a data format for the exchanging and integration of biological pathways data. By using BioPAX (Demir *et al.*, 2010) data representation format, the data integration reduces to a semantic mapping of the data over the BioPAX, data model. Thus, data exchange makes it possible to obtain uniform pathway data spread in several databases. BioPAX is a computer-readable OWL-based language for representing and exchanging models in a unique and universal format. The W3C Web Ontology Language (OWL) (Bechhofer, 2009; Dean *et al.*, 2004) is a Semantic Web language designed to represent rich and complex knowledge about things, groups of things, and relations between things. OWL is a computational logic-based language such that knowledge expressed in OWL can be exploited by computer programs, for example, to verify the consistency of that knowledge or to make implicit knowledge explicit. The adoption of BioPAX to store, exchange, and share data, would help to solve the problems of interoperability. In this way, users would be better capable of spending more time on research task rather than on struggling with data format issues.

Biological Pathway Exchange BioPAX

BioPAX is a machine-readable data format to represent and exchange biological Pathways data. Specifically, BioPAX is focused on describing systems where biological entities are involved in, and by the processes that occur over time. An example of this are biological pathways, gene regulation networks and so on. BioPAX can represent models including cell signaling pathways, metabolic pathways, biochemical reactions, gene regulation, and many others. BioPAX allows to describe biological pathways in a formal and computable format that can be analyzed rigorously by using scientific methods. Moreover, BioPAX allows to represent biological pathways as well as states of physical entities, generic physical entities, gene regulation and genetic interactions. The primary goal of BioPAX is to provide a standard format, to make easy exchange, store and integrate biological pathways data. BioPAX is a modular language, consisting of a comprehensive core that can be used alone.

The last version of BioPAX is BioPAX Level 3, that extends BioPAX including states of physical entities, generic physical entities, gene regulation and genetic interactions. BioPAX Level 3 supports the representation of many pathway data available in public databases. The modular core of BioPAX consents adding new features in an easy way. BioPAX Levels are designed to coexist, i.e., BioPAX Level 3 does not make Level 2 and Level 1 obsolete.

The core of BioPAX ontology is based on level and, has been developed to provide an easy and simple instrument to represent biological pathways. The fundamental element of the BioPAX ontology is the root class element. Thus, each level has been designed for the representation of specific types of pathway data, adding a new child component to the root class element. BioPAX Level 1 has been developed to represent only metabolic pathway data, trying to encode other kinds of pathway data with BioPAX Level 1 is possible but may not produce good outcomes. BioPAX Level 2 expands the scope of Level 1, including the representation of molecular binding interactions and hierarchical pathways. BioPAX Level 3 adds support for representation of signal transduction pathways, gene regulatory networks, and genetic interactions.

To get more detailed information it is possible to visit the following web-site: BioPAX.org (see Relevant Website section).

BioPAX Level 3 Ontology Structure

The BioPAX Level 3 ontology presents 5 essential classes: *Entity* class that is the root level and its four child classes: *Pathway*, *Interaction*, *PhysicalEntity* and *Gene*. Let analyze more in detail root class and its child classes.

- Entity class represents a single biological unit used to describe pathways, and comprises the following attributes: *Comment* attribute is used to better describe the data contained into the class. Since an element could have more than one name has been defined the *Synonyms* attribute, to handle multiple name identifier for an element. To track the source of data, the entity class presents the *dataSource* attribute, that contains a description of the data-source origin. Scientific evidence are handled by the *evidence* attribute whereas, multiple external references to the entity are defined by using the *xref* attribute. Finally an entity class can be identified by a name, characteristic managed by using the *name* attribute.

The name attribute contains the standard name and a short name useful to use in graphical contexts.

- Pathway class represents a network of interactions, comprising the following attributes: a pathways is a network of interactions, those interactions are represented by using the *pathwayComponent* attribute. The order with which these interactions happen in the pathway are handled by the *pathwayOrder* attribute. In addition Pathway class presents the availability, comment, dataSource, evidence, name, xref attributes that have the same meaning of the same attribute stated in the Entity class.
- Interaction class describes the interactions between two or more entities. The attribute *interactionType* allows to annotate the interaction by using, i.e., its name. In particular the annotation is usefull to be human-readable and cannot be used for computing tasks. Since an interaction can involve more elements, the involved elements are handled by the *participant* attribute. In addition Interaction class presents the availability, comment, dataSource, evidence, name, xref attributes that have the same meaning of the same attribute stated in the Entity class.
- PhysicalEntity class represents a set of entities, each one with its own physical structure. *cellularLocation* attribute specify a cellular location, i.e., cytoplasm whose characteristics are obtained by referring to Gene Ontology. *feature* specifies the only relevant features for the physical entity, i.e., binding site. *memberPhysicalEntity* attribute should be used to create generic groups of physical entities, however it is recommended do not use this attribute. *notFeature* attribute used to describe lacking features of the physical entity. In addition PhysicalEntity class presents the availability, comment, dataSource, evidence, name, xref attributes that have the same meaning of the respective attribute belonging to the Entity class.
- Gene contains information related to the inheritance properties. The organism where the gene has been found is handled by the attribute *organism*. In addition Gene class presents the availability, comment, dataSource, evidence, name, xref attributes that have the same meaning of the same attribute stated in the Entity class.

To get more information on all the other subclasses available in BioPAX Level 3, it is recommended to consult the BioPAX level 3 documentation available at the following web address: Biopax.org/release/biopax-/level3-documentation.pdf.

BioPAX Level 2 and Level 1 Ontology Structure

The BioPAX Level 2 and Level 1 ontology present 4 core classes: *Entity* class that is the root level and its three child classes: *Pathway*, *Interaction*, *PhysicalEntity*. Let analyze more in detail root class and its child classes.

- Entity class is used to represent a single biological element, i.e., pathway, and comprises the following attributes: *Comment* attribute is used to better describe the data encompassed in the class. The *Synonyms* attribute is used to handle multiple name for this element. To track the source of data provenance, the entity class presents the *Data-Source* attribute containing a text description of the source of provenance of this data, i.e., a database. Multiple external references to the entity are defined by using the *xref* attribute. The *name* attribute contains the full name of this element. *Short-Name* attribute contains the abbreviation of the full name, useful in a visualization context to display the name as label of a graphical element that represents this entity. All attributes that are defined in this class and are not inherited.
- Pathway class is a network of interactions, comprising the following attributes. The *pathwayComponents* attribute contains the set of interactions in this pathway or network. The *organism* attribute encompass information about the organism, i.e., *Felis-catus*. *Data-Source* attribute contains a text description of the source of provenance of this data, i.e., a database. Multiple external references to the entity are defined by using the *xref* attribute. *name* attribute contains the full name of this element. *Short-Name* attribute contains the abbreviation of the full name, useful in a visualization application to label a graphical element that represents this entity. Scientific evidence are handled by the *evidence* attribute. The *pathway Components*, *evidence* and *organism* attributes are defined in this class, whereas the other are inherited.
- Interaction class describes the interactions between two or more entities. Since an interaction can involve more elements, the involved elements are handled by the *participant* attribute. *Data-Source* attribute contains a text description of the source of provenance of this data, i.e., a database. Multiple external references to the entity are defined by using the *xref* attribute. *name* attribute contains the full name of this element. *ShortName* attribute contains the abbreviation of the full name, useful in a visualization context to display graphically the name of the element that represents this entity. The *participants* and *evidence* attributes are defined in this class, whereas the other are inherited.

- PhysicalEntity class represents a set of entities, each one with its own physical structure. *cellularLocation* attribute specify a cellular location, i.e., cytoplasm obtained by referring to Gene Ontology. *feature* specifies the only relevant features for the physical entity, i.e., binding site. *memberPhysicalEntity* attribute should be used to create generic groups of physical entities, however it is recommended do not use this attribute. *notFeature* attribute used to describe lacking features of the physical entity. Other attributes are availability, comment, dataSource, evidence, name, xref. The attributes defined in this class, are all inherited.

To get more information on all subclasses available in BioPAX, it is recommended to consult the BioPAX level 3 documentation available at the following web addresses: BioPAX.org (see Relevant Website section).

In brief, the most significant changes in BioPAX Level 3 respect to BioPAX Level 2 and Level 1 regard the following aspects. The PathwayStep class has been added as an attribute into the pathway class. Also, have been added a new class called BiochemicalPathwayStep, a child class of PathwayStep, making possible to order the biochemical processes. The physicalInteraction, which stores molecular interactions, has been moved to be a child of the Molecular Interaction class. Also, the openControlledVocabulary class has been renamed ControlledVocabulary, making possible to define a class for each controlled vocabulary. Finally, the confidence class has been renamed as Score, making it more flexible and suitable to describe genetic interactions. The major improvement introduced by BioPAX level 3 are the following: Better support for physical entities in diverse states: Proteins from sequence database like UniProt, IID and so on, are now expressed as a ProteinReference. ProteinReference stores the protein sequence, name, external references, and potential sequence features (similar in purpose to the class protein in BioPAX Level 1 and 2). The real proteins wrapped in a complex or present in a particular cellular compartment, in BioPAX Level 3 are represented through the class Protein (that is comparable in purpose to the class physicalEntityParticipant in BioPAX Level 1 and 2). Furthermore, stoichiometry attribute in this distribution is part of Conversion class, avoiding to duplicate proteins, as was done with physical Entity Participants in Level 1 and 2). Making it easier to create different types of protein without to duplicate common information to all kinds. Sequence features and stoichiometry have been significantly changed. Whereas DNA, RNA, and small molecule, have been redesigned. Only Complex has not been modified. Conversely, with the new design, the physicalEntityParticipant class has been removed, as it is no longer needed. BioPAX level 3 introduced a support to define generic physical entities, i.e., such as binding sites. That can be represented using the EntityReference class, or also supported using the EntityFeature class and its memberFeature property. BioPAX Level 3 can represent Gene regulation networks, by representing their target. Genetic interaction representation is possible in BioPAX level 3 through the GeneticInteraction class, which contains a set of genes and a phenotype (expressed using PATO or another phenotype controlled vocabulary).

BioPAX Condensing Example

In this section, are discussed how the known biological pathways contained into the organisms are encoded, stored, exchanged, visualized and analyzed by using BioPAX format. Pathway data models in BioPAX are generally encoded by using plain text as conveyed in Code 3.1. Code 3.1 shows how the pathways in the Mus-Musculus organism are coded by means of the BioPAX Level 3 format. Analyzing in detail the pathway data conveyed in Code 3.1 it is worth to note that data are encoded by using Resource Description Framework (RDF) that was developed to provide a meta language data model to the web. Nowadays, RDF is used as a standard data model for the Web of Data and the Semantic Web to support the representation, access, constraints, and relationships of objects of interest in a given application domain. Ontologies and their elements are identified using Internationalized Resource Identifiers (IRIs). URIs represent common global identifiers for resources across the Web and locally into the BioPAX file.

Code 3.1. In Figure is partially displayed (for space reason) the known biological pathways belonging to the Mus-Msculus organism. The data are retrieved from Reactome database and are encoded by using BioPAX Level 3 format.

The main advantages to represent biological pathways data by means of BioPAX is that, data can be analyzed by means of computational approaches. As well as can be visualized from all the application compatible with the BioPAX file format. In [Fig. 1](#)

Fig. 1 Reactome Pathway Viewer.

is depicted the network of the biological pathways present in the Mus-Musculus organism, by using the web platform called Pathway browser available in the Reactome web site (see Relevant Website section).

In the top left viewer interface of Reactome Pathway Browser, are located buttons to provide basic navigation, zooming, and screen arrangement actions. On the top right are located some buttons to get in an easy way the illustration, export options, and pathway overview. In the left corner of the canvas, there is the navigation panel of the pathway browser (to have in one-shot a full pathway view), instead of on the right corner; there are the buttons to navigate the pathway and zoom in-out. The central canvas displays the pathway, making possible to navigate it by clicking and dragging or zooming. To get information regarding the shown elements, simple move the mouse over each node or edge and automatically the browser will show short information regarding the selected item. Clicking on the selected item will be highlighted in the event hierarchy situated on the left site of the canvas. From the event hierarchy, it is possible to go more into detail regarding the selected element. When a pathway is chosen in the canvas, in the tab "Download" will be shown some buttons to download the pathway in several formats, for reuse or reference. Formats include Word, PDF, SBML, SBN, BioPAX 2, BioPAX 3. Moreover, from the tab situated under the canvas, it is possible to get details of the select item in the Pathway Browser. For example, when a reaction is selected, will be shown details including molecules, summary and references, evidence and so on. The tab "Molecules" provides details regarding all the molecules involved with the selected one. If an item is selected in the diagram, the corresponding molecules are highlighted. The tab "Details" shows details for the selected item in the pathway diagram. For reactions, if available reaction diagrams from the Rhea database are retrieved and visualized. For simple molecules, information from ChEBI are extracted and visualized. For pathway items that contain proteins shows, 3D structure from PDB if available. Finally, the tab "Expression" displays gene expression information for genes corresponding to the selected item into the canvas. Expressions data are obtained from the Gene Expression Atlas. Over the canvas are located some tabs "Analysis," "Tour," and "Layout." The "Analyze" tab allows experimental data to be loaded, or paste text data, i.e., a sequence in the text-area. Following the step user will be guided to the results, that will be shown in a tabular format into the Analysis tab situated under the canvas. The "Layout" allows to users to chose what elements of the Reactome pathway browser to visualize or not. The "Tour" tab gives to the user a video guide explaining how to use the Pathway Browser.

Pathway Databases Using BioPAX

At today, BioPAX is used in several public pathways databases, as format to encode pathways data. Below is a list of the major biological pathways database that use BioPAX for pathway data encoding. The BioCyc ([Caspi et al., 2008](#)) databases contains metabolic and signaling pathways data encoded by using BioPAX Level 3. Data stored in BioCyc are computationally predicted. BioCyc provides tools for navigating, visualizing, and analyzing the underlying databases, and for analyzing omics data, to get access to data and tools provided by BioCyc subscription is required.

The BioModels ([Le Novère et al., 2006](#)) database contains models of biological processes. BioModels contains 630 manually curated models and 983 non curated models, providing access to 112,898 Metabolic models, 27,531 Nonmetabolic models and 2641 Whole genome metabolism models. The access to the model archives is free to everyone. Data in BioModel are encoded by using SBML and BioPAX Level 2.

EcoCyc ([Keseler et al., 2005](#)) is a scientific database for the bacterium *Escherichia coli* K-12 MG1655. EcoCyc provides access to literature-based curation of the entire genome, and of transcriptional regulation, transporters, and metabolic pathways. Metabolic and Signaling Pathways are encoded by using BioPAX, Level 3 and the access is free for everyone.

Kyoto Encyclopedia of Genes and Genomes KEGG ([Kanehisa and Goto, 2000](#)) is a Pathway database for understanding and analyzing gene functions, and linking genomic information providing utilities to understand how the biological systems work. Data in KEGG are encoded by using the BioPAX Level 1. The KEGG system is available free for academics purposes.

MetaCyc ([Caspi et al., 2008](#)) is a curated database of experimentally metabolic and signaling pathways. MetaCyc contains 2526 pathways from 2844 different organisms. Pathways data in MetaCyc are encoded by using the BioPAX Level 3. The MetaCyc is freely available for each user.

NetPath ([Kandasamy et al., 2010](#)) is a manually curated resource of signal transduction pathways in humans. Data in NetPath are available for download in BioPAX level 3.0, PSI-MI version 2.5 and SBML version 2.1 formats. The NetPath system is freely available for use.

Pathway Commons (see Relevant Website section) ([Cerami et al., 2011](#)) is a web resource for biological pathways data analysis, store and exchange. The access to Pathway Commons is free, data access are freely available under the licence terms of each involved database. Data are stored and retrieved by using BioPAX.

Reactome (see Relevant Website section) ([Croft et al., 2014](#)) is an open-source, curated and peer reviewed Metabolic and Signaling pathway database. The goal of Reactome is to provide intuitive bioinformatics tools for the visualization, exchanging, interpretation and analysis of pathway. Data are encoded by using BioPAX file format.

Rhea (see Relevant Website section) ([Alcántara et al., 2012](#)) is a freely available resource of curated biochemical reactions. It has been designed to provide a set of chemical transformations for applications such as the functional annotation of enzymes, pathway inference and metabolic network reconstruction. Data in Rhea are available in several different file format for the download in particular pathways data are encoded by using BioPAX Level 2. All data in Rhea is freely accessible and available for anyone to use.

Models for Computable Phenotyping

Alfredo Tirado-Ramos and Laura Manuel, University of Texas Health at San Antonio, San Antonio, TX, United States

© 2019 Elsevier Inc. All rights reserved.

Introduction

The need for the creation of health research networks that comprise healthcare and pharmaceutical organizations, and are able to collaborate in order to facilitate clinical trial design and patient accrual, is currently driving a strong push in academic and industrial research. This push is being translated into federated clinical big data grids and their associated querying mechanisms. One of the fastest related growing fields of interest for researchers in this field is the design and development of technologies and processes for seamlessly querying logically and geographically dispersed patient data and metadata resources for cohort creation in such networks, while complying with diverse local and global governance requirements for patient data privacy. The currently de facto standard approach is called *computable phenotyping*, and is based on a varied ecosystem of technologies and tools for creating virtual organizations that share patient metadata in real time, while also allowing for participation in multi-site collaborations with local, state, national or international healthcare organizations. Computable phenotypes allow for well-defined processes for deepening phenotype querying, analysis and data de-identification, while pipelining the development of study protocols.

Background

A computable phenotype can be best described as a set of inclusion and exclusion criteria for a patient cohort. Criteria should be specific and objective enough to turn them into a machine-readable query, yet also generalized enough to make them portable between different data sources. Mere verbal descriptions are neither a computable phenotype, nor are they a set of proprietary vendor codes for a specific electronic health record. Nevertheless, a list of standardized medical terminology codes (ICD, HCPCS, LOINC, NDC, etc.) could be a computable phenotype.

Computable phenotypes are necessary for characterization of cohorts and reproducibility of clinical research. Yet currently, *Electronic Health Record* (EHR) systems do not have the ability to create and distribute computable phenotypes that can be utilized across multiple sites for research reproducibility. Standardized solutions are needed and are being defined. But even if a EHR vendor develops a system similar computable phenotype tool to existing open source program, they do not have a compelling reason to make such tools usable across platforms.

One of the utmost challenges, then, is to produce and make available such tools and algorithms for querying patient data in an open and scalable way, for applications ranging from clinical trial patient accrual to queries used for preparatory research work.

Several tools have been generated for creating and consuming computable phenotypes, each with their own strengths and weaknesses. These include OMOP, PCORNet Front Door, i2b2, and SHRINE, among others ([i2b2, 2017](#); [OMOP, 2017](#); [PCORnet, 2017](#); [SHRINE, 2017](#)).

Applications

There are a few research groups, mostly based in the United States, that are working on developing standardized solutions and tools for building scalable computable phenotype application frameworks. One such application framework is the set of tools developed by the *Patient-centered Research Institute* (PCORI), a research initiative started by the Obama administration focused on novel technologies and methods that stress patient-centered outcomes. Through the use of their *Common Data Model* (CDM) PCORI has created both a way of distributing queries via their main query tool, as well as a standardized format for research data warehousing, which provides a consistent framework for writing queries ([PCORnet, 2018](#)). In a quarterly manner, PCORI distributes queries throughout its national distributed network, that review data warehouses for consistency and compliance to its rules. By utilizing this standardized data warehouse PCORI can write a single query language script (e.g., SAS) or query and expect it to run without error on every instance of a data warehouse. PCORI leverages a number of relevant standards (ICD, HCPCS, RXCUI, NDC, etc.) as well as their own standardized data set to create reproducible computable phenotypes across its collection of data warehousing clusters, or *Clinical Data Research Networks* (CRDNs).

While PCORI's idea of a computable phenotype implementation is one of the most widely deployed across the United States, it is not the only one. Tool-specific approaches such as [i2b2 \(2017\)](#) allow for the straightforward creation of reproducible computable phenotypes, ranging from academic institutions' bare bones instantiations as well as at pharmaceutical industry-driven sophisticated frameworks. For instance, at the University of Texas Health San Antonio we have invested considerable resources into generating and processing computable phenotypes, analyzing the most efficient and concise manners through which they can be created and distributed. As specific context, we work on computable phenotypes for research grants, e.g., for our *Clinical and Translational Science Awards* (CTSA) Collaborative Innovation Award for surgical outcome disparities, as well as with a

number of externally-initiated clinical trials within our participation with the international TriNetX network and diverse national research groups.

In general, research groups like ours that are working on computable phenotyping face a number of serious limiting factors, such as hiring and training of skilled programmers with the ability to work with medical data, training medical researchers to understand the limitations of *Electronic Health Record* data, and coordinating with the local teams to correctly construct computable phenotypes out of raw data. That is, it is often necessary to train a cadre of scientists (both MD and PhD) to understand enough about the limitations and capabilities of medical data to be able to make effective use of computable phenotypes in their research, in an increasingly independent manner. Such scientists do their part by learning how to construct eligibility criteria and design studies that leverage their skills, expertise and needs in order to understand where specific technical support is needed.

Analysis

One of the main challenges in applying a computable phenotypes is the alignment of computable terms. It seems surprising that something as simple as a medication, e.g., “Tylenol[®]” would be complicated to process in an Electronic Health Record, but Tylenol[®] (acetaminophen) is an ingredient that can be found in more than 100 brand names and 200 drug combinations. Thus it becomes important for researchers to decide if a particular brand of Tylenol[®] or every medication that contains the ingredient acetaminophen, should be used in a particular computable phenotype. A mapping tool (e.g., RXNav) which can pull up all of the medications and their associated codes, may be necessary to find all brand names and combinations. Laboratory tests, diagnosis, and procedures all have similar issues, some of which can be solved through the use of international coding standards (e.g., ICD9, ICD10) or proprietary coding schemes (e.g., CPT), but even the use of these standardized coding schemes may present issues. That is, if a researcher provides a phenotype with just ICD9 codes, it might happen that these codes do not map exactly to ICD10 codes, and thus cause the potential for mapping errors. Medicare uses medical billing codes for procedures (e.g., CPT), however these codes are proprietary, so finding a list of applicable procedure codes can be difficult both for the researcher and for the technician trying to translate the query to their local site. Terms may be sent as free text such as: “Bariatric surgery” and leave the query writer to look up everything they can translate as bariatric surgery. But this also brings in the issue of the query builder needing to make decisions about the exact codes to be used. However, query builders are generally computer programmers with little to no medical knowledge who then would have to make decisions about medical terminology, which should be best left in the hands of medical coders, nurses and physicians.

A large part of our analysis at the University of Texas Health Science Center includes information that is not stored in the Electronic Health Record such as socioeconomic data (education, job, and relations) or difficult to extract from certain types of data. For example, many physicians do not code family or medical history diagnosis in the Electronic Health Record system and instead write them within unstructured, free-text notes. Free-text notes may contain *Protected Health Information* (PHI) and require specialized handling. They may also require complex *Natural Language Processing* programming, or manual curation to convert them into a structured format usable by researchers and data analysts.

Additionally, the limitations of Electronic Health Records should be taken into account when attempting to construct a “control” group. Electronic Health Records contain the necessary data for clinics or hospital departments in order to treat their current patient properly, but they may not contain crucial data for indepth research. Care must be taken to ensure that control groups are matched, not just by their lack of a diagnosis, but in the treatment areas they visited. An otolaryngologist would have no need to code diagnosis about infertility or other diagnosis that do not apply to their practice, and thus patients who have only visited a specialist outside of the scope of the targeted diagnosis should be excluded from control cohort selection. Thus the absence of a diagnosis in the Electronic Health Record system cannot be considered the absence of a condition.

The study of data quality metrics is a very important area within data analysis, which is in need of vigorous research and development. The Electronic Health Record system may or may not apply constraints on elements like plausible dates, foreign key constraints, or maintaining consistency between the various identifiers. Corrupted patient data can lead to invalid data such as one patient’s laboratory data being associated with another patient’s visit or account data. Variation in the structure of the Electronic Health Record system, the documentation habits of physicians and other healthcare workers who enter or structure data within the system, and the usage of coding schemes across sites provide increased complexity to the task of composing a computable phenotype for use across multiple sites.

Another important challenge is the conception of a coherent and technically informed vision with the input from all stakeholders about how informatics in general and computable phenotypes in particular could serve combined goals of research, quality improvement, and business intelligence. It requires the teamwork of experts from various disciplines to create a data warehouse that can provide researchers with access to high quality data; it should be noted that research data warehouses may provide deceptively easy access to complex data in a rapidly evolving discipline.

Case Study

A particularly descriptive case study on the development and use of computable phenotypes in the real world is provided by the ADAPTABLE trial by PCORI ([ADAPTABLE Home, 2017](#)). The ADAPTABLE trial is a first of its kind, looking at the benefit/risk ratio for different dosages of aspirin, weighing the risk of bleeding vs the benefit of reduced cardiac events, and it involves most of the nationwide Clinical Data Research Networks considerable resources. The initial ADAPTABLE phenotype was distributed with a text description

Fig. 2 A section of the refined code created from the final ADAPTABLE phenotype. This phenotype contained lists of codes that removed the guess work out of building the query. Localized corrections for data quality issues may still be required, such as incorrectly entered lab values. This code was designed to work on the PCORI CDM tables. Reproduced from PCORnet Common Data Model (CDM), 2018.

controlled by the hospital's quality and informatics teams which provide an audit trail. Depending on the method of managing these changes, erroneous data may persist in the database even if it is not visible to caretakers.

Electronic Health Record data is by nature, incomplete. Physicians are paid to treat patients, not to maintain accurate problems lists, thus problems that have been resolved are often not removed from the database and simply persist until someone removes or otherwise remedies them. Patients may still have a broken bone in their record months or years after the injury has fully healed. Additionally, physicians have no incentive to add structured diagnosis data to a patient's record to indicate conditions which they are not treating the patient for. Insurance only reimburses for problems that the physician is treating, not for the completeness of the medical record.

A patient may have been diagnosed with conditions that have not been added to their records. Some researchers erroneously consider health data for a patient to be "complete" and assume that if a patient has been diagnosed with a condition that it is in the chart: an Ear Nose and Throat (ENT) specialist may not pay much attention to the fact that a patient may be infertile, since it may not affect his work; similarly, a fertility specialist may not pay much attention to the fact that a patient presents a deviated septum.

The quality of a phenotype definition requires a developer experienced with electronic medical records and cross disciplinary faculty who can bridge the expertise gap between the developers, the clinicians, the statisticians, and other scientists working on a project. Reviewers who can vet the queries are needed for objective, reliable performance metrics, and validation. The state of diagnostics has improved greatly over the last half decade, but much work remains to be done. There need to be subject matter experts who can recognize disease characteristics beyond explicit diagnoses, leveraging quantitative measures and indicators of disease including laboratory results, vital signs, and medication prescribing patterns insofar as they can be extracted from the Electronic Health Record. Different tactics may be optimal depending on whether the condition of interest is chronic, acute, or transient. These tactics will not necessarily be applicable at different healthcare organizations which have different approaches for the handling of chronic, acute, or transient problems.

Future Directions

The ability to identify novel research approaches for the creation of health research networks that comprise healthcare and pharmaceutical organizations is becoming increasingly dependent of the manner in which we create, develop and deploy computable phenotypes. Such computable phenotypes, once defined, should be applicable to multiple research problems utilizing multiple institution's data. There is indeed a need for a set of standardized processes and tools like those mentioned before, which can be leveraged when developing reliable phenotypes that are not sensitive to the specific enterprise Electronic Health Record vendors or institutions. Academic approaches that line up queries and reviews of the structure and consistency of a common data model, as it takes place in the PCORnet network, are a positive step forward. In these approaches queries are distributed to test common quality issues such as multiple patient's data being coded to the same hospital visit, resulting in improved quality within the data warehouses of participating institutions. Nevertheless, real channels by which to communicate the problems and solutions back to the enterprise Electronic Health Record teams are sorely needed.

Unlike system vendors, academic researchers do not divert their limited resources from solving scientific and engineering obstacles to focus on marketing. As a consequence, there will be a consistent bias toward over estimating the value of proprietary solutions and underestimating the value of open source solutions produced by researchers. Furthermore, vendors have strong economic incentives to not make their methodology transparent, reproducible, portable or interoperable. One way for institutions to protect themselves against vendor lock-in and data-blocking is to embrace not only open source, open standards compliant software but also for decision makers to educate themselves about the business models and collaborative practices that make open source software possible, so successful, and rapid in its evolution. We at the University of Texas Health Science Center have used our computable phenotyping capabilities for projects that include national collaborative research on network governance, surgical outcome disparities, Amyotrophic Lateral Sclerosis, Weight and Health, Antibiotics and Childhood Obesity, and so forth. Our efforts, as in many other small to medium size research outfits, have been mostly limited by the difficulty of recruiting and retaining faculty and staff programmers with the required skillset, and the very nature of work consisting in constructing computable phenotypes out of raw Electronic Health Record data.

Closing Remarks

Our own successful experience with this technology since 2014 has helped our Electronic Health Record system become more usable and relevant to our researchers, while helping our collaborative efforts with our external partners as well as our local clinical trials office. A pragmatic leveraging of such new resources has been of great importance for our institution to advance the design of studies and clinical trials with 21st century technology, and bring our clinicians and other stakeholders onboard. If the impact of data completeness issues and the preventable within-institutional siloing of business versus research informatics can be eventually overcome, there would be tremendous benefits seen for published studies, clinical registries, coordination of patient care, and fiscal sustainability of institutions by minimizing waste, readmission, complications and errors.

It is our belief that the ability to identify cohorts of people with particular health conditions, across healthcare organizations, by using common definitions has proven to have an intrinsic value for clinical quality measurement, health improvement, and research.

Acknowledgments

The authors would like to acknowledge the i2b2 transSMART foundation, PCORnet, and Harvard Catalyst for their contributions to open source computable phenotype platforms and the National Library of Medicine for its strides in producing and compiling standardized ontologies for medical science.

Biographical Sketch

As the chief and founder of the Clinical Informatics Research Division of the University of Texas Health Science Center at San Antonio, Dr. Tirado-Ramos leads a full-spectrum biomedical informatics program and explores the intersection between informatics, translational science, and clinically relevant data-centric problems including, but not limited to, computable phenotype-based research in health disparities, obesity, amyotrophic lateral sclerosis, ageing, and cancer. Under the umbrella of successful PCORI awards, he created and maintains an information research system for interdisciplinary collaboration between pediatric endocrinologists, cancer researchers and neurologists, creating new institutional governance frameworks along the way. He also co-directs the informatics core at the Claude Pepper Older Americans Independence Center, a National Institute on Aging award, where he works on state of the art informatics infrastructures to investigate innovative interventions that target the aging process as well as aging-related diseases, with a major focus on pharmacologic interventions. Previous to arriving at the University of Texas, he served at Emory University School of Medicine as Associate Director for the Biomedical Informatics Core at the Center for AIDS Research at the Rollins School of Public Health.

Laura Manuel received her BS in Computer Science from the School of Science at the University of Texas San Antonio. She works as the lead developer in the Clinical Informatics Research Division at the University of Texas Health Science Center San Antonio and oversees the work of the development team. She oversees the processing and deidentification of clinical data for the CIRD clinical data warehouse, has done research with geospatial analysis and is currently working on agent base simulation for HIV transmission.

Introduction

The strong data-driven and integrative nature of research in genomic, interactomics, and proteomics in the post genomic era, has been spurred by the continuing developments of high-throughput experimental assays and their capabilities in data-generation (Loman *et al.*, 2012). Advances in high-throughput innovative technologies continue to support the exponential growth in public and private available genomic data, interactomics data, and proteomics data. Thus, the integration and interpretation of these immense volumes of data could increase of some order of magnitude the enhancements in health and clinical outcomes, representing a challenge to move genomic, proteomics, interactomics research in the clinical activities (Kanehisa *et al.*, 2011). Even the extraction of information from the tissue through images is becoming an high-throughput methodology. In fact, considering the actual high resolution of microscopy, Radio-Magnetic Indicator (RMI), and Positron Emission Tomography (PET), bioimages present an high resolution that might allow the retrieval of phenotypic information that could be measured precisely and be linked to underlying molecular profiles and clinical outcome. Thus, high-throughput image analysis could serve as a suitable vector to assist clinical diagnosis and tissue-based research (Veta *et al.*, 2014; Caicedo *et al.*, 2009; Gurcan *et al.*, 2009). To promote such a large-scale image and integration analysis it is mandatory to develop scalable databases able to store a massive amount of data based on the NoSQL model, allowing to manage and query image analysis results systematically and efficiently. Thus, to process and analyze these various kinds of data it is necessary the support of computer scientists as well as of statisticians, physics and so on. Data obtained by the experimental high-throughput assays contains bias and noise. Indeed, it is mandatory to clean and uniform the input data, to be used in the knowledge extraction phase. Data clean is known as pre-processing, it is a step of the data mining process. Pre-processing is an iterative methodology that has to be performed many times demanding for a lot of computational power. A significant advantage of the preprocessing phase is that it can be easily parallelized which drastically reduces computation times thanks to the huge computational power that is available on various parallel computers. How highlighted by the previous examples, different kinds of data require different types of analysis and thus they are likely to have different computing requirements. The analysis of next-generation sequencing (NGS), a de novo assembly analysis step, might require vast quantities of RAM memory compared to a BLAST search, which needs less memory but is a CPU-bound process that, for the time to complete a BLAST job, is much more limiting than the speed of the CPU. Data analysis is thus tailored through a combination of resources availability, capacity, and configuration. On the other hand, to analyze high-resolution images of whole tissue slides, researchers need to outline spatial regions into the images representing these regions, as a set of values obtained from the pixels, which can be translated in the form of geometric shapes, surfaces, and fields. Modeling this spatial information provides the support for robust and scalable spatial queries. To support the massive data and computational demands of image analysis algorithms, a solution could be to employ high performance computing techniques to speed-up the image analysis (Kikinis *et al.*, 1998). The application can be built to exploit the modern hybrid computing systems equipped with multi-core CPUs and graphics processing units (GPUs). For example, the connection with the database from which run the query can be handled by the CPU, whereas the features extraction from the retrieved image can be done on the GPU. Because, GPUs provide high-speed memories and extensive multi-processing capabilities, which typically exceed those of CPUs, GPUs are perfect for performing massive parallel imaging analysis. Some of those challenges may be overcome by ad-hoc computational techniques. But still computational power and the efficiency remains the principal bottleneck that limits the execution of such analyses. Although the cost of hardware is decreasing considerably in recent years, investments of thousands of dollars are usually necessary to build and maintain a scientific computing infrastructure. For individual researchers and small labs, who not could have access to large funding, acquiring, configuring, and keeping working the required computing infrastructure is a hindrance and even a barrier to advance research. In addition to the hardware costs and maintenance, advanced software to facilitate parallel computation is typically needed, and a team must be hired to develop and maintain the software on the computing infrastructure. A possible alternative for buying and maintaining one's own computer cluster could be to use computational resources 'in the cloud', e.g., Amazon Web Services. In the recent years, cloud computing has risen as a viable option to quickly and easily obtain computational resources needed for analysis (Bajo *et al.*, 2010; Calabrese and Cannataro, 2016). Cloud computing offers network access to computational resources where CPUs, memory, and disks are accessible in the form of a virtual machine (i.e., a complete operating system) that a user has individual and full control on it. As a result, cloud computing has the potential to allow simple access to a variety of different types of machines, including large-memory machines, fast-CPU machines, or abundant disk space, without needing to build and later maintain the given infrastructure. There exist different forms for providing cloud resources such as the Infrastructure as a Service (IaaS) model. The virtualization technology allows entire operating systems to run independently of the underlying hardware. Due to the low level resources that such a model exposes, and the flexibility with which users can arrange the available components, a wide variety of configurations can be obtained. This feature primarily removes limitations imposed by physical resource availability and helps to enable open-ended analyses. In this way, to the user is given access to what seems to be a typical server computer. However, the server is just a 'virtual machine' running at any one point on the underlying hardware architecture, which is made up of many independent CPUs and storage devices. In the Software as a Service (SaaS) model, users can use the

applications provided by the cloud provider infrastructure, without exorbitant capital costs or infrastructure preparation efforts. SaaS provides to the users remote access to the resources, usually through a web browser. Users need not worry about storage or application management as only specific parameters are enabled for the users' control. Just in some cases, it is possible for the users to manage particular configurations of the application. Platform as a Service (PaaS) is a service model whereby users control the applications deployed, but not the underlying infrastructure. Applications need to be created using programming languages, libraries, services and tools supported by the provider that constitute the development platform provided as a service. An example is Google Apps Engine, which allows developing applications in Java and Python and supplies for both languages the software development kit (SDK). In this way, Cloud computing potentially provides an efficient and low-cost means to achieve the power and scale of computation required to facilitate large-scale efforts in data integration and analysis.

Recent studies showed that cloud computing and HPC are playing a strategic role in the improvement of healthcare services and biomedical research. In fact, they are making it possible to carry out and accelerate radical biological and medical breakthroughs that would directly translate into real benefits for the community.

The remaining of the manuscript is arranged as follows: Section "Parallel Architectures" describes the main parallel architectures used in current computers and suitable to run parallel programs. Section "Distributed Architectures" describes the most used distributed architectures with special focus on Bioinformatics. Section "Programming Languages for Parallel Architectures" summarizes the most used programming languages to write parallel code and illustrates some simple examples introducing how to write simply parallel code, through the presented languages. Section "Programming Languages for Distributed Architectures" introduces the main languages for writing distributed applications to be run on distributed architectures, such as Internet and the Cloud, and provides some simple examples on how to write distributed code. Section "Parallel and Distributed Bioinformatics" presents some uses of Cloud computing and high performance computing in computational biology, bioinformatics, and life sciences. Finally, Section "Closing Remarks" reports some closing remarks.

Parallel Architectures

The amounts of data obtained by new experimental technologies are growing exponentially in size (Marx, 2013; Aronova *et al.*, 2010). Besides, every minute scientific knowledge increases by thousands of pages and to read the new scientific material produced only in a single day, a researcher would take several years. To follow the produced scientific outcomes regarding a single disease, i. e., breast cancer, a researcher would have to examine more than a hundred different journals and data repositories and he/she has to read a lot of manuscripts per day. For example, genome sequencing gives precise information on the basic constituents of life; this massive quantity of data calls for a shift from a reductionist approach to a whole systematic view of biological systems. The whole systematic view of biological systems allows to produce an accurate description of the components and the interactions among them, leading to a better understanding of living systems, only if supported by efficient and scalable algorithms. Thus, the needs of computationally intensive applications able to deal with huge amount of data arise (O'Driscoll *et al.*, 2013). Parallel, distributed and cloud computing architectures are the perfect instruments to produce efficient and scalable tools to help scientist to spur light on biological systems.

Flynn Taxonomy

Flynn taxonomy (Flynn, 2011) identifies 4 classes of computers, taking into account only the instruction and data streams without considering the parallel machine architecture. To understand how the Flynn's taxonomy can classify parallel architectures through the data and instruction streams, it is necessary to understand how the instruction cycle of the CPU works. A generic statement in a program is composed of two parts *operands* and *opcode*. An opcode is used as the value of the statement, whereas the operands represent the address of memory where the data are stored. The CPU's instruction execution cycle comprises the following steps: (i) in the first step the address of the statement to be executed is calculated. (ii) In the second step the statement is fetched (a single statement at time is fetched), then (iii) the current statement is decoded by the Decoder. (iv) The operands address is calculate, thus (v) the fetch of the operands is possible, (vi) the statement is executed, (vii) the result is stored. (viii) If there are more statements jump to (i) otherwise stop. Thus, it can be asserted that the instruction streams includes the instructions executed by the CPU, whereas the data streams contain the data (operands) required for the execution of the instructions. Thus Flynn's classification is based on the multiplicity of the instruction streams and data streams performed by the CPU during the program execution.

- SISD – Single Instruction Single Data, in this category machines are conventional sequential computers that process only one stream of instructions and one stream of data at time by a single CPU, e.g., classical Von Neumann architectures.
- SIMD – Single Instruction Multiple Data, in this structure, multiple processing units (Arithmetic Logic Units – ALU) work under the control of a single Control Unit (CU). All the ALU of this organization receives the same instruction broadcast from the CU. Each ALU takes the data from its own memory, and hence it has on distinct data streams. An example of a dedicated SIMD processor is the GPU that relieves the CPU from time-consuming calculations related to the three-dimensional visualization.
- MISD – Multiple Instructions Single Data, In this class the work of multiple ALU is coordinate by multiple CUs. Each CU is supervising one instruction stream and elaborating it through its corresponding ALU, processing one data stream at the time.

All the CUs communicate and coordinate through the common shared memory for the arrangement of the single data stream. At this class belongs the vector processors, but most often said to be an empty class.

- MIMD – Multiple Instructions Multiple Data, autonomous processors execute simultaneously different instructions on different data. MIMD category comprises the general parallel machines e.g., computer clusters.

Multicore Computers

In a multicore computers, a single CPU is made up of several computational cores. Each core has its own instruction and data memories (i.e., L1 caches) and all cores share a second level on-chip cache (i.e., L2). The CPU is also connected through the bus to the main memory and all the system's peripherals. Furthermore, the L2 cache could be shared between sub-sets of cores, e.g., in a quad cores CPU, there are two L2 caches that are shared by two group of two cores, or is shared by 2 units of 4 cores in an octa-core CPU. Indeed, the external memories are often grouped into multiple levels and use different storage technologies.

Multiprocessor Computers

Multiprocessor Computers can be partitioned in three main architectures SMP, cluster and hybrid.

- A Shared Memory Multiprocessor (SMP) parallel computer consists in a multiprocessor system where, each processor has its CPU and cache, sharing the same central memory and peripherals. A parallel program executed on an SMP parallel computer allows to run multiple threads of one process, on each available processor. The process's program and data are stored in the shared main memory, in this way all the thread in the same process can use the shared memory to communicate. The communication among threads happens reading and writing values into the shared memory data structures.
- A cluster of computers consists of multiple interconnected computational nodes. In general, a cluster presents a dedicate node called frontend, from which users can log in to compile and run their programs, while the backend nodes do the computation. Each backend has its CPU, cache, main memory, and peripherals, such as a local disk drive. Moreover, each backend node is equipped with a dedicated high-speed backend network. The backend network is used only to allow communication between the nodes of the cluster. Other network traffic, i.e., remote logins goes to the frontend. Conversely, from an SMP parallel computer, there is no global shared memory, each backend node can access only its local memory. The cluster computer is known as distributed memory model. In a parallel cluster computer, a parallel program runs in parallel on each backend node. All processes perform its computation independently in its local environment, storing its results in the data structures in its local memory. If one process needs a piece of data that belong to another process's memory space, the process that owns the data sends a message containing the data through the backend network to the process that required the data. Conversely, from the SMP parallel program where the threads can merely access shared data in the shared memory space, in a cluster parallel program, the access to shared data must be explicitly coded enabling nodes to exchange messages among them.
- Hybrid parallel computers cluster and SMP models coexist together. In this architectures are present both shared memory (in each node) and distributed memory (among the nodes). A parallel program in a hybrid architecture runs on separate backend nodes with its central memory space. Moreover, each process has multiple threads, which like in an SMP parallel computer each thread can run on each local CPU. Thus, threads in the same process share the same memory space and can access their own shared data structures directly. Threads belonging to different backend nodes must send messages to each other to communicate in order to share information.

Graphic Processing Unit (GPU)

In recent years, much has been made of the computing industry's widespread shift to parallel computing. Today all consumer computers, smartphones, and tablets will ship with multicore central processors, and graphical process units are making parallel computing not to be only relegated to cluster, supercomputers or mainframes. GPU (Graphics Processing Units) computing (Owens *et al.*, 2008) is relatively new compared to CPU computing, essentially GPUs of early 2000 were developed to handle the color of every pixel on the screen by using a programmable arithmetics units called *pixel shaders*. Because all the arithmetics on input color, text pixel coordinate and so on was controlled by programmer, researcher notice that was possible to handle any data. Thus, have been coined the GPGPU General Purpose term. Because each pixel can be computed independently, the GPU typically presents an architecture with multiple processing cores making possible to calculate multiple pixels in parallel. In response, GPUs became a general-purpose massively parallel coprocessors to perform arbitrary computations on each kind of data. In this way, GPU performs non-rendering tasks by making those tasks appear as if they were a standard rendering (Pharr and Fernando, 2005).

Distributed Architectures

A distributed architecture consists of multiple programs running on various computers as a single system (Sunderam, 1990). The computers belonging to a distributed system can be physically close together and connected by a high-speed network, e.g., cluster, or they can be geographically distant and connected by a vast area network, e.g., a Grid of computers. A distributed architecture can

comprise any possible kind of machines, such as mainframes, workstations, minicomputers, and so on. Distributed architectures aim to hide the underlying computer network by producing a collaborative parallel environment, perceived by the user as a single computer (Rumelhart *et al.*, 1987).

Grid

A computer Grid presents an architecture similar to the clusters, except that the computational nodes are spread over the world and connected through a combination of local area networks and the Internet, instead of that nodes are connected on a single dedicated backend network (Bote-Lorenzo *et al.*, 2004). Grid applications often involve large amounts of computing and/or data. For these reasons, grid offers effective support for the implementation and use of Parallel and distributed computing systems (Cannataro and Talia, 2003a,b, 2004). Grid programming follows the same theoretical approach as cluster computers, with the only difference that programs run on grid machine spread over the internet network. But a parallel program that performs fine on a cluster does not mean that is suitable for the grid. Indeed, on the internet, the latency is orders of magnitude larger than a typical cluster's backend, and the internet's bandwidth is smaller than the cluster backend network. Thus, the messages exchanged among the Grid's nodes are sent over the internet need longer time respect communication in the cluster. Therefore well-suited problems for the Grid are those can be split into many independent pieces and computed independently among the nodes with a meager rate of communication. SETI@home (see "Relevant Websites section") (Search for Extraterrestrial Intelligence) project, and the Great Internet Mersenne Prime Search (GIMPS) (see "Relevant Websites section"), both are examples of a well-suited projects for the Grid environment. SETI@home is a scientific experiment, born at UC Berkeley, that uses Internet-connected computers in the Search for Extraterrestrial Intelligence. Users can participate by downloading and installing a free program that downloads and analyses radio telescope data. GIMPS is a scientific project aimed to discover Mersenne's prime numbers. A Mersenne's prime numbers is defined as: $2^P - 1$ where P is the exponent to be tested. Thus, if $2^P - 1$ is prime, P must also be prime. Thus, the first step in the search of Mersenne's prime number is to create a list of prime exponents to test. Both projects belong to the "voluntary computing" Grid model. In the voluntary computing model, users have to download a client software program and install it on his/her computer. The installed software is low-priority that exploits the idle CPU's cycles to execute parallel computation downloading data from the home site and synchronizing with the other nodes over the networks. In addition to the voluntary computing Grid, usually, a grid is set up by a consortium of companies, universities, research institutions, and government agencies. Examples are, the open source Grid project and Globus Toolkit (see "Relevant Websites section"), and the Open Science Grid (OSG) (see "Relevant Websites section"). Globus allows researchers and people to share computing power, databases. Globus includes software services and libraries for resource monitoring, discovery, and management, plus security and file management. The Open Science Grid (OSG) is a grid devoted to large-scale scientific computation, with thousands of institutional processors located in several countries, to facilitate the access to distributed high throughput computing for research.

Cloud

Cloud computing can be perceived as an evolution of the Grid computing, with the inclusion of virtualization and sharing of resources (Mell *et al.*, 2011). Distributed and Grid computing have long been employed for high-performance computing and scientific simulation and now Cloud computing architecture is becoming an attractive platform for scientific researchers and their computing needs. The World Wide Web (in short, WWW) spurs the development of web-supported services even known as web-services, where a user may request services through a website of the service provider, and the service provider provides the requested service. Examples of services on the web are: Buying an airline ticket or purchase a book from an e-commerce provider. An information system that supports service implementation is called service-oriented information system. An architecture that provides support for the implementation of web-services is known as Service-Oriented Architecture (SOA). With the integration of cloud computing and service-oriented computing, the services are now provided through a cloud. These services are not only related to booking travel or hotel, but they also include infrastructures as a service (IaaS), Platform as a Service (PaaS) and Software as a Service (SaaS). Thus, Cloud Computing provides to the customers Softwares, Platforms and Infrastructures as a service via the Cloud (Zhang *et al.*, 2010). The idea behind cloud computing is to provide computing, infrastructures, and platform as a service in a very simple way just like we use electricity, or gas as a service. Thus, a cloud service supplier offers different types of service to the consumer. The service could be to use the cloud for computing, for database management, or for application support big data analysis such as biological data. The technological advances that characterize Cloud Computing respect to distributed computing and SOA, it is its adaptability to customer demand. Users can request new applications and infrastructure on demand. Indeed Clouds or, Cloud Computing is much more than accessing applications using the pay per view on-demand model. Cloud computing provides a virtual high-performance computing (HPC) or a high-performance environment for scientific simulations that can be handled through a simple web-browser (Buyya *et al.*, 2009). One of the major's keystones of Cloud resources is their quick access and easy-to-use nature. In fact, HPC resources have to be set up by expert figures with specific skills. Indeed, these skills are not widespread among all the possible users because HPC resources set up vary quite significantly. Also, a supercomputer will offer an environment tailored to dig with large parallel scientific applications, only after that the several different versions of compilers and libraries are available to users and software is kept up-to-date as part of the service, requiring a precise version of the operating system.

Furthermore, HPC systems present restrictive regulation policies to handle the resource (Mishra *et al.*, 2013). Given the shared nature of the resources among several users all competing for them, manage them through a scheduling system is mandatory. The resources that a user might employ are regulated by the scheduling system, and the policies are implemented through the scheduling system by the owners/operators of the infrastructure, for each user are necessary. Thus, scheduling policies have to take into account the number of active processes and how long a single process can run. The most used fashion in HPC is set a runtime threshold for all the computational process, after that the process is killed. Consequently, users have to adapt their programs to cope with the maximum runtime threshold by regularly saving data to disk to enable restart if the application is ended. These changes have a cost, both regarding the computational resources used (saving output data can require a long time to have written on disk) and, the increasing effort in the development necessary to modify programs to undertake this functionality. Cloud resources, on the other hand, generally have no such restrictions. User purchase computing resources are paying for them running them for as long as it is required. Users can also purchase as many resources as needed, dependent upon the available resources in the Clouds, and the associated cost. Indeed, cloud vendors, e.g., Amazon, Microsoft supplies computational resources via Cloud, which can be bought by anyone, just creating an account and paying for their use. To have access to an NGS analysis suite on the cloud users have to look for the service, for example, AWS (see “Relevant Websites section”) available on Amazon create an account and start to use the service. In this way is the Cloud environment to keep the different versions of compilers and libraries up-to-date as well the opportune version of the operating system. Finally, setup and usage of Cloud resources can be more straightforward than HPC, especially for less experienced users, the higher level of control over the environment by Graphical User Interface offers some advantages, to unskilled users to quickly reach their computing simulation needs.

Programming Languages for Parallel Architectures

A parallel program can be written by using a parallel programming language. Programmers to write parallel multithreaded programs can use the standard POSIX thread library (Pthreads) using the C language, whereas in Java programmers can use the native Thread class. If programmers execute this code on a shared memory parallel computer, each thread will run on a different processor simultaneously, yielding a parallel speedup. A better and more straightforward approach to write parallel programs is to use parallel programming libraries. Parallel libraries simplify the process of writing code abstracting low-level thread details reducing the effort needed to write a parallel program. Writing low-level multi-threads applications, it requires a great deal of effort to write the code that sets up and synchronize the multiple threads of an SMP parallel programs to ensure the consistency of information. Bioinformatics programmers are interested in solving problems in their domains, such to search a massive DNA sequence database or to predict the tertiary structure of an unknown protein, and they are not interested in writing low-level thread code. Indeed, many programmers may lack the expertise to write multi-thread code. Instead, parallel programming library encapsulates the low-level multi-thread code that is the same in any parallel program, presenting to the programmer easy-to-use, high-level parallel programming abstractions. In this way, programmers can focus on solving the domain problem by using the facilities provided by the parallel programming libraries.

Shared Memory

OpenMP (see “Relevant Websites section”) is the standard library to write parallel programming on a shared memory architectures. The first version of OpenMP was published in 1997 for the Fortran language and subsequently in 1998 for the C, and C++ languages, the latest version available today of OpenMP is the 4.5 released in 2015. The OpenMP API provides only user-directed parallelization, wherein the programmer explicitly defines the actions to be taken by the compiler and runtime system in order to execute the program in parallel. Standard OpenMP does not support Java. OpenMP is compatible with C, and C++, although these languages natively support multithread programming. Conversely, from C, and C++, Fortran language does not support multithreaded programming, a program wrote in Fortran can be made multithreading only by using OpenMP by inserting special OpenMP keywords called *pragmas* in the source code. OpenMP Pragmas are available even in C and C++, making easy to create multi-thread programs. By adding pragmas, programmers are designing which section of the program has to be parallelized, to be execute by multiple threads. When programmer located all the sections of code that is necessary to be executed in parallel, it is needed compile the annotated source code through an appropriate OpenMP compiler. The OpenMP compiler, finding the OpenMP pragmas through the code, rewrites the sequential source code in parallel code, adding the necessary low-level threading code. As the final step, the compiler compiles the now-multithreaded program as a regular Fortran, C or C++ program, that can be run as usual on an SMP parallel computer. Here is reported a simple example that explain how to use OpenMP pragmas. As example, suppose that it is necessary to figure out all the shortest path in a biological pathway. We can use the Floyd-Warshall’s algorithm. The sequential code is conveyed in [Listing 1](#).

Using the input presented in [Listing 2](#), we get the following output let see [Listing 3](#).

To make the same code be able to be execute on multiple threads we need to add in the code the OpenMP pragmas, as conveyed in [Listing 4](#).

Thus adding the OpenMP pragmas in the correct position in the code quickly we transform a sequential program in a parallel program. The “*#pragma omp parallel*” specifics to the compiler the start of a piece of code that can be executed in parallel on multiple threads. Because the number of threads is not specified in the pragma, the number of threads is defined at runtime. Inside

```

void floydWarshall(int graph[][VERTICES_COUNT]){
int distance[VERTICES_COUNT][VERTICES_COUNT];
for (int i = 0; i < VERTICES_COUNT; i++)
    for (int j = 0; j < VERTICES_COUNT; j++)
        distance[i][j] = graph[i][j];
        for (int k = 0; k < VERTICES_COUNT; k++){
            for (int i = 0; i < VERTICES_COUNT; i++){
                for (int j = 0; j < VERTICES_COUNT; j++){
                    if (distance[i][k] + distance[k][j] < distance[i][j])
                        distance[i][j] = distance[i][k] + distance[k][j];
                }
            }
        }
    Print(distance);
}

```

Listing 1 Floyd-Warshall's procedure.

```

int graph[VERTICES_COUNT][VERTICES_COUNT] = {
    { 0, 5, INF, 10 },
    { INF, 0, 3, INF },
    { INF, INF, 0, 1 },
    { INF, INF, INF, 0 }
};
FloydWarshall(graph);

```

Listing 2 Floyd-Warshall's Input example.

OUTPUT: Shortest distances between every pair of vertices

```

0    5    8    9
INF  0    3    4
INF INF  0    1
INF INF INF  0

```

Listing 3 Floyd-Warshall's output example.

the parallel region, each thread gets its copies of the i , j , and k variables, the other variables $VERTICES_COUNT$ and $DISTANCE$, which are declared outside the parallel region, are shared. All the threads execute the external cycle. However, when they reach the middle cycle, the “*for pragma*” states that the middle cycle is to be executed as sharing parallel cycle. That is, the iterations in the middle cycle are partitioned among the scheduled threads, so each thread executes a subset of iterations. Because no cycle schedule is specified, a default schedule is used. Thus, implicitly each thread at the end of the middle loop do an implicit wait, before proceeding to the next outer loop iteration.

```

#pragma omp parallel
void floydWarshall(int graph[][VERTICES.COUNT]){
    int distance[VERTICES.COUNT][VERTICES.COUNT];
    for (int i = 0; i < VERTICES.COUNT; i++)
        for (int j = 0; j < VERTICES.COUNT; j++)
            distance[i][j] = graph[i][j];
        for (int k = 0; k < VERTICES.COUNT; k++){
            #pragma omp for
            for (int i = 0; i < VERTICES.COUNT; i++){
                for (int j = 0; j < VERTICES.COUNT; j++){
                    if (distance[i][k] + distance[k][j] < distance[i][j])
                        distance[i][j] = distance[i][k] + distance[k][j];
                }
            }
        }
    Print(distance);
}

```

Listing 4 Floyd-Warshall's OpenMP parallel version.

```

#include <iostream>
__global__ void kernel( void ) {
}

int main( void ) {
    kernel<<<1,1>>>();
    printf( "Hello ,_World!_in_CUDA\n" );
    return 0;
}

```

Listing 5 Hello world code in CUDA.

CUDA

CUDA (see “Relevant Websites section”) is a parallel computing platform and application programming interface (API) developed by Nvidia. A CUDA program consists of host and device code. Usually, the host (CPU) executes the parts of the program that present low parallelism, i.e., the data partition among the device’s cores, whereas the statements with high data parallelism, they are performed in the device code. The NVIDIA C compiler (*nvcc*) extracts the two parts during the compilation process. The host code is ANSI C code, and it is further compiled with the host’s standard C compilers to be executed on an ordinary CPU. The device code is written using ANSI C at which are added keywords called kernels, for labeling data-parallel functions, and their associated data structures. The device code is typically additionally compiled by the *nvcc* to be executed on a GPU device. The kernel functions (or, kernels) generate a high number of threads to employ data parallelism. The CUDA threads are different from CPU threads because CUDA threads are of much lighter weight than the CPU threads. Thus, to generate and schedule CUDA threads require less cycle respect to create and schedule CPU threads that need thousands of clock cycles. These differences are due to the efficient hardware support of CUDA’s architecture. [Listing 5](#) introduce a very simple *Hello world* program in CUDA.

The differences between a standard hello world program and hello world in CUDA are: An empty function called `kernel()` and the keyword `__global__`, and a call to the “`kernel <<<1,1>>>()`” function.

The `__global__` qualifier informs the compiler that the function has to be compiled to be executed on the device instead of the host.

As example, suppose that we need to sum two sequence of genes expression to detect if the sum of the expression for each genes is over a threshold. We can model the problem as sum of two vectors. In particular we write the sum function to be execute on the device by using CUDA.

In the [Listing 6](#) we used `cudaMalloc()` to allocate the three arrays. Using `cudaMemcpy()`, we copy the input data from the host to the device with the kernel `cudaMemcpyHostToDevice`, and we copy back the results from the device to the host with by using the kernel `cudaMemcpyDeviceToHost`. Finally, by using `cudaFree()`, we release the allocated memory. The annotation `<<<N,1>>>` added to the `add()` methods, it allows to execute the `add()` method in the device code, from the host code in `main()`. Let see the meaning of the two parameters in the triple angle brackets annotation. Let define a simple CUDA kernel `cudaKernel <<<nBlocks, nThreadsPerBlock>>>` the first parameter `nBlocks` defines the number of thread blocks, and the second parameter `nThreadsPerBlock` defines the number of threads within the thread block. Launching the following kernel `<<<2,1>>>()`, the number of simultaneously running threads is given by the product of both parameters that is equals to 2 in this case. Launching the following kernel `<<<N,1>>>()` we are running `N` copies of kernel code, but how can we know which block is currently running? By using `blockIdx.x` to index arrays, each block handles different indices, thus Kernel can refer to its block. More example and more details on CUDA programming can found at the CUDA's web site provided in “Relevant Websites section”, and in [Sanders and Kandrot \(2010\)](#) and [Kirk and Wen-Mei \(2016\)](#).

Message Passing

Message Passing Interface (MPI) is a standard application program interface (API) with which write parallel programs in a distributed environment by sending and receiving messages. The first version of MPI has been released in the 1994 supporting Fortran and C. The MPI supports Fortran, C, and C++. Like OpenMP, even MPI is not compatible with Java. MPI does not require particular compiler; it is just a message passing protocol for programming parallel computers. Parallels programs are writing using the MPI library routines as needed to send and receive messages. Programs are executed on parallel cluster computers through an appropriate MPI launcher program. The MPI API takes care of all the low-level details, i.e., setting up network connections between processes and transferring messages back and forth. Conversely, form OpenMP that uses pragmas to specify to the compiler which section of code has to be parallelized, in MPI there no needs to use any tag in the code. MPI programmers write Fortran, C, and C++ code, as usual, including or importing the MPI library, and adding through the program the calls to the MPI subroutines to send and receive messages among the nodes. The final code is compiled using the Fortran, C or C++ standard compiler. To execute the compiled program on a parallel computer, it is mandatory use a specific MPI launcher application. In this way, the launcher takes care to run the program in multiple processes on the nodes of a cluster. We'll use OpenMPI (see “Relevant Websites section”) to present the programming examples in this section.

As simple example in [Listing 7](#), we report a cluster parallel program for the “HelloWorld” algorithm in MPI by using C++.

To compile the code in [Listing 7](#), open the terminal application go to the folder containing the “HelloWorldMPI.cpp” file and type the command in [Listing 8](#):

When the compiling process is done to run the program type the command in [Listing 9](#):

Programming Languages for Distributed Architectures

This Section summarizes some relevant programming approaches for distributed architectures, including the RESTful model, Hadoop, MapReduce and Globus.

Restful Model

REpresentational State Transfer REST is an architectural style established to develop, create and organize distributed systems. The term REpresentational State Transfer REST has been coined in 2000 by Roy Fielding in his doctoral thesis (see “Relevant Websites section”) REST is only an architectural style for building scalable web services; it is not a standard guidelines to follow in order to obtain a RESTful architecture ([Rodriguez, 2008](#)). In RESTful systems, communication occurs over the Hypertext Transfer Protocol (HTTP). Because REST is resource-based architecture, REST exploits the HTTP methods with which access to the resources. In REST resources are identified through a Unified Resource Identifier (URI), and resource should be compatible with the HTTP standard operations. Resources in REST have different representations, e.g., text, XML, JSON, etc. By using uniform resource identifiers (URIs) and HTTP verbs, it is possible to perform actions to the resources. If we define the resource “/office/agents”, it is possible to retrieve information about an agent resource by using the HTTP verb *Get*, create a new agent resource utilizing the HTTP verb *Post*, update an existing agent resource using the HTTP verb *Put*, and delete an agent resource through the HTTP verb *Delete*. Web service APIs that follow the REST architecture style, they are known as RESTful APIs. RESTful APIs uses XML and JSON as the data format

```

#include <iostream>
#include <stdio.h>

for exchanging data between client applications and servers. AS example, in [Listing 10](#) we present a RESTful web services wrote in Java by using (Jersey/JAX-RS) APIs.

The class *HelloWorld* registers itself as a get resource by using the *@GET* annotation. Using the *@Produces* annotation, it defines that it can deliver several Multipurpose Internet Mail Extensions (MIME) types such as plain text, XML, JSON and HTML. *@Path* annotation defines the URI *"/HelloWorld"* where the service is available. MIME type is a standard with which to denote the nature and format of a document in internet.

```
import javax.ws.rs.GET;
import javax.ws.rs.Path;
import javax.ws.rs.Produces;
import javax.ws.rs.core.MediaType;

@Path("/HelloWorld")
public class HelloWorld {

    // This method is called if TEXT_PLAIN is request
    @GET
    @Produces(MediaType.TEXT_PLAIN)
    public String helloWorldPlainText() {
        return "Hello_WORLD";
    }

    // This method is called if XML is request
    @GET
    @Produces(MediaType.TEXT_XML)
    public String helloWorldXML() {
        return "<?xml version='1.0'?>" + "<hello>_Hello_WORLD" + "</hello>";
    }

    // This method is called if HTML is request
    @GET
    @Produces(MediaType.TEXT_HTML)
    public String helloWorldHTML() {
        return "<html>_" + "<title>" + "Hello_WORLD" + "</title>"
            + "<body><h1>" + "Hello_WORLD" + "</body></h1>" + "</html>_";
    }

    // This method is called if JSON is request
    @GET @Produces(MediaType.APPLICATION_JSON)
    public String getMyBean() {
        return {"id":1,"content":"HelloWorld!"} ;
    }

}
```

Listing 10 The HelloWorld web server in Java by using (Jersey/JAX-RS).

Hadoop

The Apache Hadoop (see “Relevant Websites section”) software library is the basis for the development of advanced distributed and scalable applications, able to deal with big data. Hadoop consists of two main components: The Hadoop Distributed Filesystem (HDFS) and MapReduce. The HDFS is a data storage as well as a data processing filesystem. HDFS is designed to store and provide parallel, streaming access to large quantities of data (up to 100s of TB). HDFS storage is disseminated across a cluster of nodes; a single large file could be stored across multiple nodes in the cluster. A file is split into blocks called chunks, with a default size of 64MB. HDFS is designed to store and handle large files efficiently. The Hadoop ecosystem now comprises several components for databases, data warehousing, image processing, deep learning, and natural language processing, are only a few example.

Mapreduce

MapReduce (see “Relevant Websites section”) is a programming paradigm that allows to process big data with a parallel distributed algorithm on clusters providing massive scalability and fault-tolerant. MapReduce application consists of two steps: the Map and Reduce step, where data are processed using key/value pairs. In the Map step, the input dataset is treated by using the specified Map function. The Map function should be designed to count the number of unique occurrences of an SNP in a dataset, for example. The Map step produces an intermediate set of key/value pairs, which are partitioned in chunks and then assigned to the Reduce function to be elaborated. The Reduce function produces the output of the MapReduce application. The MapReduce framework consists of a master the ResourceManager, and one slave the NodeManager per single cluster-node. The ResourceManager is the master node, it accepts job submissions from clients, and it starts the process called ApplicationMaster to run the jobs, assigning the resources required for a job. A ResourceManager consists of two elements: Scheduler and ApplicationsManager. The Scheduler allocates resources and does not participate in running or monitoring the job. The ApplicationsManager accepts the job submissions from the clients and starts the ApplicationMaster to execute the submitted job and to restart failed ApplicationMaster. The ApplicationMasters are application specific, with one ApplicationMaster for each task. The NodeManager runs resource containers on the machine and monitors the resource usage of the applications running in the resource containers on the computer, reporting the resource usage to the ResourceManager. [Listing 11](#) shows a simple example of using MapReduce to count the occurrence of SNPs in a given dataset.

Globus

The open source Globus Toolkit (see “Relevant Websites section”) is a set of tools useful for building a grid infrastructure. The toolkit includes software services and libraries for resource monitoring, discovery, and management, plus security and file management. Globus Toolkit consists of three main components that are: Resource management, Data management, and Information Services. All the three components are built on top of the Grid Security Infrastructure (GSI), providing security functions, including authentication, confidential communication, authorization, and delegation. The resource management component provides support for, resource allocation, remote jobs submission, to collect results and monitoring job status and progress. Globus Toolkit does not have its job scheduler to allocate available resources and to dispatch jobs to proper machines. Globus Toolkit provides the tools and APIs necessary to implement its own scheduler. The information services component provides API and interfaces for collecting information in the grid by using the Directory Access Protocol (LDAP). The data management component provides support for transfer files among machines in the grid and for the supervision of these transfers.

Parallel and Distributed Bioinformatics

Classically High-performance computing (HPC) has been used in physics, mathematics, aerodynamics and so on, scientific areas where an intensive computational power it is necessary. Nowadays, HPC is being used even more often in Life Sciences, Medical Informatics, and Bioinformatics, to face the increasing amount of available experimental data ([Cannataro, 2009](#)). Current computational and systems biology involve a large number of biological data sources and database disseminated all over the world wide web, requiring efficient and scalable algorithms able to analyze these vast amounts of available experimental data. Besides, the intensification of use of high-throughput experimental assays, such as Next Generation Sequencing, microarray, Genome-Wide Study (GWAS) and mass spectrometry (Mass spectrometer), are producing massive volumes of data per single experiment, contributing significantly to increase the amount of data generated daily. Indeed, the storage and analysis of such data are becoming a bottleneck to bring to light useful knowledge hide in these apparently unrelated data. Thus, the developing of high-performance computing HPC is mandatory to make it possible to handle this vast amount of data, to be suitable in clinical practise or to develop tailored treatments for a single patient based on its own genetic features. Grids have been thought as universal tools whose aim is to provide a general solution for building scalable and ubiquity parallel collaborative environments. However, the high flexibility in the application of the Grid has limited the use of Grids only in the field of information technology. Indeed, the use of Grid-toolkits with which to develop Grid-services requires advanced computer skills. Thus, to encourage the use of grids in specific sectors, several dedicated Grids have been designed. The aim of dedicated Grids within a particular application domain is to provide ready to use Grid-services able to face the specific requirements and problems of that field. In the last times, many applications of Bioinformatics and Systems Biology have been developed on the Grids. The term BioGrids refers to the

import org.apache.hadoop.mapreduce.lib.output.FileOutputFormat;

public class SNPCount {

    public static class SNPMapper
        extends Mapper<Object, Text, Text, IntWritable>{

        private final static IntWritable iw = new IntWritable(1);

    private Text snp = new Text();

    public void map(Object key, Text value, Context context
        ) throws IOException, InterruptedException {
        StringTokenizer itr = new StringTokenizer(value.toString());
        while (itr.hasMoreTokens()) {
            snp.set(itr.nextToken());
            context.write(snp, iw);
        }
    }
}
```

Listing 11 The SNP occurrences count application in Java by using MapReduce.

deployment of bioinformatics analysis pipeline to the Grid, yielding to a high-performance computing infrastructure dedicated to solve biomedical and bioinformatics problems exploiting the services of the Grid (Ellisman *et al.*, 2004). BioGrids goal is to provide the software and network infrastructures for Virtual Collaborative Laboratory integrating bioinformatics, biological and medical knowledge, through easy access and use of the Grid resources; integrated access to biological databases; and finally the support to application modeling and design, usually provided through workflow modeling.

Also, even Clouds are employed to host and deploy bioinformatics applications. Recent researches indicated that cloud computing could enhance healthcare services and biomedical study (Ahuja *et al.*, 2012; Rosenthal *et al.*, 2010), by allowing new potentialities. A significant thrust toward the adoption of Cloud in healthcare and bioinformatics is the growth of big data produced by high-throughput assays (Greene *et al.*, 2014). Because the amount of digital genomics, interactomics information increase, develop tools with the capability to dig with this flow of data is mandatory. Buried in this data there are the knowledge to extract to make clinical advances actuality, but at today that are not very accessible to the clinical researchers. Cloud Computing might enable data sharing and

```

public static class SNPReducer
    extends Reducer<Text,IntWritable,Text,IntWritable> {
    private IntWritable result = new IntWritable();

    public void reduce(Text key, Iterable<IntWritable> values,
        Context context
        ) throws IOException, InterruptedException {

        int sum = 0;
        for (IntWritable val : values) {
            sum += val.get();
        }
        result.set(sum);
        context.write(key, result);
    }
}

public static void main(String[] args) throws Exception {
    Configuration conf = new Configuration();

    Job job = Job.getInstance(conf, "SNP_count");
    job.setJarByClass(SNPCount.class);
    job.setMapperClass(SNPMapper.class);
    job.setCombinerClass(SNPReducer.class);
    job.setReducerClass(SNPReducer.class);
    job.setOutputKeyClass(Text.class);
    job.setOutputValueClass(IntWritable.class);
    FileInputFormat.addInputPath(job, new Path(args[0]));
    FileOutputFormat.setOutputPath(job, new Path(args[1]));

}
}

```

Listing 11 (Continued).

integration at vast scale in an easy and simple way. The volume of data produced by Medical imaging might reach the magnitude of petabytes due to high-resolution of the imaging instruments. Consequently, it is evident that the cloud computing will provide a possible contribution to satisfy computational needs related to the reconstruction and analysis of medical images, allowing a full sharing of imaging as well as advanced remote analysis. The cloud computing represents a solution for the problems of storing and processing data in the context of bioinformatics. Therefore, classical computational infrastructures for data processing have become ineffective and hard to maintain. The traditional bioinformatics analysis requires to download public data (e.g., NCBI, Ensembl), and the download and installation of the proper software or more than one with which to analyze the downloaded data. By porting data and software in the cloud, it is possible to provide them as a service, obtaining a level of integration that improves the analysis and the storage of bioinformatics big-data. In particular, as a result of this unusual growth of data, the requirement of data as a service (Data as a Service, DaaS) is of absolute importance. DaaS provides data storage in a dynamic virtual space hosted in the cloud, allowing users to update data through a browser-web. An example of DaaS is the Amazon Web Services (AWS) (see “Relevant Websites section”) ([Fusaro et al., 2011](#)), which provides a centralized repository of public data sets, including data from GenBank, Ensembl, 1000 Genomes Project,

Unigene, and Influenza Virus. There have been several efforts to develop cloud-based tools known as Software as a Service (SaaS), to perform several bioinformatics tasks through a simple web-browser. In this way, researchers can focus only on the definition of the data analysis methodology without worry about if the hardware available is powerful enough for the simulation and avoiding to take care of software updating, managing, and so on. Example of SaaS are: Cloud4SNP (Agapito *et al.*, 2013) is a private Cloud bioinformatics tool for the parallel preprocessing and statistical analysis of pharmacogenomics SNP DMET microarray data. It is a Cloud version of DMET-Analyzer (Guzzi *et al.*, 2012), that has been implemented on the Cloud employing the Data Mining Cloud Framework (Marozzo *et al.*, 2013a), a software environment for the design and execution of knowledge discovery workflows on the Cloud (Marozzo *et al.*, 2013b). Cloud4SNP allows to statistically test the significance of the presence of SNPs in two classes of samples using the well known Fisher test. ProteoCloud (see "Relevant Websites section") (Muth *et al.*, 2013) is a freely available, full-featured cloud-based platform to perform computationally intensive, exhaustive searches using five different peptide identification algorithms. ProteoCloud is open source, including a graphical user interface, making easy to interact with the application. In addition to DaaS and SaaS there are the Platform as a Service PaaS. The most known and used bioinformatics platform in the cloud is the Galaxy Cloud (see "Relevant Websites section"). Galaxy cloud-based is a platform for the analysis of big volume of data, allowing to the users customize the deployment as well as retain complete control on the instances and the associated data. The current version of Galaxy is available on Amazon Web Services. Another example of PaaS is CloudMan (see "Relevant Websites section") allows bioinformatics researchers quickly deployment, customize, and share of their entire cloud analysis environment, along with data, tools, and configurations.

Closing Remarks

High performance computing, distributed systems and database technology play a central role in Computational Biology and Bioinformatics. High-throughput experimental platforms such as microarray, mass spectrometry, and next generation sequencing, are producing the so called *omics* data (e.g., genomics, proteomics and interactomics data), that are at the basis of Computational Biology and Bioinformatics. These big omics data have an increasing volume due to the high resolution of such platforms and because biomedical studies involve an increasing number of biological samples. Moreover, the digitalization of healthcare data, such as laboratory tests and administrative data, is increasing the volume of healthcare data that is coupled to omics and clinical data. Finally, the use of body sensors and IoT (Internet of Things) devices in medicine is another source of big data. This big data trend poses new challenges for computing in bioinformatics related to the efficient preprocessing, analysis and integration of omics and clinical data. Main technological approaches used to face those challenges are: high-performance computing; Cloud deployment; improved data models for structured and unstructured data; novel data analytics methods such as Sentiment Analysis, Affective Computing, and Graph Analytics; novel privacy-preserving methods. This articles surveyed main computing approaches used in bioinformatics, including parallel and distributed computing architectures, parallel programming languages, novel programming approach for distributed architecture and Cloud.

Computing Languages for Bioinformatics: Perl

Giuseppe Agapito, University “Magna Graecia” of Catanzaro, Catanzaro, Italy

© 2019 Elsevier Inc. All rights reserved.

Introduction

Perl is a general-purpose scripting language introduced by Larry Wall in 1987 (Wall *et al.*, 1994, 2000). Perl was developed to connect different languages and tools together by making compatible the various data format between them. The reasons to spur Wall to create Perl have been, to gather together all the best features of C, C++, Lisp, awk, Smalltalk 80, Pascal and Unix Shell languages without their disadvantages. Perl became very popular as server-side script language, but with the time extended its application domain from system administrator tasks, managing databases, as well as object-oriented programming, finance, bioinformatics, and Graphical User Interface (GUI) programming. Perl is not an acronym, although we can refer to PERL as “Practical Extraction and Reporting Language.” The language used to develop Perl is C, Perl is a cross-platform language, and it is available to download under the General Public Licence (GNU). Perl is available to download at the following website: www.perl.org. At the time of writing, the current stable version of Perl is the 5.24.1. The major strength points of Perl are the following: (i) Perl is easy to learn and use, as it was designed to be easy to understand especially for humans rather than for computers. (ii) Perl is portable in the sense that, it is possible to run a script wrote in Windows operating system on several different other operating systems without change any line of code. Perl is a partially interpreted language since existing a compilation step through that a Perl script goes through before its execution. Before to execute a Perl script, is mandatory to compile the script that is translated in bytecode and finally, Perl interprets the bytecode. In Perl the compilation includes many of the same optimization steps like in Java, C, and C++ program, that is the elimination of unreachable code, replacing of constant expressions by their values, linking library and the built-in functions, and so on. Another characteristic of Perl is that variables do not have an intrinsic type in the sense that, conversely from languages such as Java, C or C++, a variable can be declared without any particular type. In this way, a variable previously used to store an integer can next be used to contain String or Double. Moreover, a variable can also contain an undefined value, by assigning to it the special object *undef*. The *undef* keyword in Perl's is the equivalent of the *null* object in Object Oriented Languages. A faster way to obtain further information regarding the Perl language features is to consult Perl's online documentation, commonly referred to as *perldoc*.

Perl is still broadly used for its original purpose: working like mediator among different tools, making data coming from one software in a format compatible with the format expected by the other tool. Going from processing and summarizing system logs (Newville, 2001), through manipulating databases (Wishart *et al.*, 2007), reformatting text files (Letunic and Bork, 2011), and simple search-and-replace operations, as well as in comparative studies (Warren *et al.*, 2010), life sciences data analysis (Ravel, 2001), handling data from the Human Genome Project as reported in Stein *et al.* (2002), Stein (1996), managing bioinformatics data see work of Arakawa *et al.* (2003), Lim and Zhang (1999) and all the tasks that require massive amounts of data manipulation.

Background

Perl is a language primarily intended to be used from command-line interface, shell or terminal because it was developed as a server-side scripting language (Wall *et al.*, 1994; Hall and Schwartz, 1998; Ousterhout, 1998). To take advantages of all the power of Perl, programmers are to know how to deal with a terminal interface. A terminal usually is a black/white screen displaying the prompt that looks like: \$, %, C:\>. After the prompt symbol, there is a flashing underscore meaning that the terminal is ready to get command. By using the terminal, it is possible to consult the Perl documentation by typing the command *perldoc*. From a terminal window type “*perldoc-h*” (the -h option prints more help) as conveyed in Fig. 1.

The *perldoc* command allows programmers to access to all the information about a particular function, including the implementation code. To get information about the *rename* function, the programmer has to type in the terminal: “*perldoc-f rename*” allowing to see the description and code of the *rename* function. As well as *perldoc* allows programmers to search for all the question-answer entries in the Perl FAQs for which the questions contain a particular keyword, for example, looking for *perldoc-q substr*” in this case the command allow to obtain more detailed information about *substr* function. The terminal is also used to write and execute Perl programs. Before to run Perl programs it is necessary to write them, by using an editor. Each operating system, Unix, OS X, Windows, and Linux, comes with several different text editors. Thus each programmer is free to use its favorite editor.

Install Perl on Your Machine

Perl has been developed to be used on many platforms. It will almost certainly build and run any UNIX-like systems such as Linux, Solaris, FreeBSD. Most other current operating systems are supported: Windows, OS/2, Apple Mac OS, and so on. Programmers can get the source release and/or the Binary distributions of Perl at the following web address <https://www.perl.org/get.html>.

```

[os-x:~ mac$ perldoc -h
perldoc [options] PageName|ModuleName|ProgramName|URL...
perldoc [options] -f BuiltinFunction
perldoc [options] -q FAQRegex
perldoc [options] -v PerlVariable

Options:
  -h    Display this help message
  -V    Report version
  -r    Recursive search (slow)
  -i    Ignore case
  -t    Display pod using pod2text instead of Pod::Man and groff
        (-t is the default on win32 unless -n is specified)
  -u    Display unformatted pod text
  -m    Display module's file in its entirety
  -n    Specify replacement for groff
  -l    Display the module's file name
  -F    Arguments are file names, not modules
  -D    Verbosely describe what's going on
  -T    Send output to STDOUT without any pager
  -d output_filename_to_send_to
  -o output_format_name
  -M FormatterModuleNameToUse
  -w formatter_option:option_value
  -L translation_code    Choose doc translation (if any)
  -X    Use index if present (looks for pod.idx at /System/Library/Perl/5.18/darwin-thread-multi-2le
vel)
  -q    Search the text of questions (not answers) in perlfaq[1-9]
  -f    Search Perl built-in functions
  -v    Search predefined Perl variables

```

Fig. 1 Using terminal to display the Perl documentation by using perldoc command.

- **Install Perl on Windows:** Make sure you do not have any version of Perl already installed. If you do uninstall Perl be sure if you still have a folder in C:\Strawberry to delete it. Download the Strawberry Perl version 5.12.3 from <http://strawberryperl.com>. Reboot your machine, after go to your start menu, then click the “Perl command” link to verify that the installation worked type: `perl-v`.
- **Install Perl on Unix/Linux:** Install a compiler (if not yet installed on your machine), such as `gcc` through your system package management (e.g., `apt`, `yum`). Open a Terminal and copy and paste the command “`curl-L http://xrl.us/installperlunix | bash`” then press `return` key to confirm.
- **Install Perl on OSX:** First, install “Command Line Tools for Xcode,” directly through Xcode, or through the Apple Developer Downloads (free registration required). Xcode can also be installed through the App Store application. Launch the Terminal Applications, copy and paste the command “`curl-L http://xrl.us/installperlunix | bash`” then press `return` key to confirm.

Write and Execute Perl Program by Using Interactive Development Environment

Despite Perl was intended to be used from terminal command line, now are available several tools that make it possible to write and run Perl program by using Interactive Development Environment (IDE). In Windows there are a plenty of IDE editors the most used are *Notepad++*, *Padre* and *Notepad* (Plain Text Editor) the link to download are available at the following web address https://learn.perl.org/installing/windows_tools.html. In Unix/Linux the most used IDE editor are *vim*, *emacs* and *Padre* you can get more information where download these editor to the following web address https://learn.perl.org/installing/unix_linux_tools.html. In Mac OSX the most used IDE editor are *vim*, *emacs*, TextEdit (Plain Text Editor), TextMate (Commercial) and *Padre*. More information about where to download these editor can get to the following web address https://learn.perl.org/installing/osx_tools.html.

Finally, users can use the NetBeans IDE wrote in Java making NetBeans platform independent that is, can run on each operating system in which Java is installed. NetBeans let users to quickly and easily develop Java desktop, mobile, and web applications, as well as HTML5, JavaScript, PHP, and CSS. The IDE also provides an excellent set of tools for PHP and C/C++ including Perl. They are free and open source and has a large community of users and developers around the world. To use Perl in NetBeans IDE is necessary to download and install the *Perl On NetBeans – plugin* from the NetBeans Plugin Portal. The *Perl On NetBeans – plugin* requires the following steps to be installed on your system for the IDE to work correctly:

- Perl v5.12 or greater installed on your machine;
- Java Runtime Environment 7 or higher installed on your computer;
- NetBeans 8 or higher installed on your computer;
- The Perl and Java binaries (in Windows system) should be available in the PATH variable.

After you match the following system requirements, the installation of *Perl On NetBeans* can be summarized in the following steps:

- Download the *Perl On NetBeans* plugin from the web site "<http://plugins.netbeans.org/plugin/36183/perl-on-netbeans>".
- In NetBeans 8 select *Tool* from the menu bar and select *Plugins*, showing the *Plugins Manager* window;
- In the *Plugins Manager* window select the *Downloaded* tab and click on the button "*Add Plugins ...*" will show the file system navigation window, to locate the *Perl On NetBeans* file (download previously);
- Select the file to add to NetBeans 8.

Write and Execute a Perl Program by Using the Terminal

Assuming that Perl is installed on the machine (if not it is mandatory to install Perl by following the instruction provided in the Perl web site (www.perl.org)), the next step is to set up a directory for all the codes where to save all the Perl programs. A Perl program will look like as depicted in Fig. 2.

Let's look more in detail line by line the program presented in Fig. 2.

The first line "`#!/usr/bin/perl`" is called *interpreter directive* (also called "*shebang*", specifying to the operating system the suitable interpreter to execute the script. Perl treats all lines starting with `#` as a comment, ignoring it. However, the concatenation between "`#`" and "`!`" at the start of the first line tells the operating system that it is an executable file, and compatible with perl, which is located at the `/usr/bin/` directory. The second line "`use warnings;`" activates warnings. The activation of warnings is useful because recall to the interpreter to highlight to the programmers possible mistakes that otherwise will be not visualized. As an example, suppose that we made the following error (print "`Perl is $Awesome !!!`") in the line 3 of the code presented in Fig. 2. Commenting the "`use warning`" line we get the following result in output (let see Fig. 3), without having any clue on why in the output misses the string "`Awesome`".

Instead, enabling the warnings visualization the perl interpreter give in out-put the message conveyed in Fig. 4. The interpreter informs the programmer that is using an uninitialized variable called "`$Awesome`" (in Perl the variables are preceded by the `$` symbol).

Fundamentals

Perl is a programming language with which it is possible to guide the computer to solve problems. Problem-solving is related to data elaboration, to elaborate data it needs to use a language that can be understood by the machine. Programming

```
#!/usr/bin/perl

use warnings;

print "Perl is Awesome !!!\n";

"firstPerlProgram.pl" 5L, 63C
```

Fig. 2 A simple Perl program wrote by using vi editor.

```
[os-x:~ mac$ ./firstPerlProgram.pl ]
Perl is !!!
os-x:~ mac$
```

Fig. 3 The output when we warnings are disabled.

```
[os-x:~ mac$ ./firstPerlProgram.pl ]
Name "main::Awesome" used only once: possible typo at ./firstPerlProgram.pl line 5.
Use of uninitialized value $Awesome in concatenation (.) or string at ./firstPerlProgram.pl line 5.
Perl is !!!
os-x:~ mac$
```

Fig. 4 The output when warnings are enabled.

languages such as Perl provide problem-solving capabilities to the computer. Perl uses statements often grouped together into blocks, that are easy to write for humans as well as are easy to be understood by machines. A Perl statement tells the computer how to deal with data, ending with a semicolon ";". To gather together any number of statements it is necessary to surround statements by curly braces {...}, that in Perl is called *block*, here's an example: "{print "Hello Perl.\n"; print "That's a block."}", this statement prints on video the message Hello Perl and That's a block, on different rows (without quotes). Statements are not enough to elaborate data, because the machine needs to store data somewhere generally into the main memory, to deal with them when it is necessary during the whole elaboration process. The memory locations where program languages store data for simplicity are identified through variables. In Perl as well as in the other program languages, a variable is defined through a name. In particular, a variable name has to start with the symbols "\$", and should not be a keyword of Perl language. For example, "\$var" is a correct name for a variable instead, "\$do" is not proper as variable name because can be confused with Perl's *do* keyword. The \$ symbol before the name makes it possible to know that the \$var is a *scalar* specifying that the variable can store a single value at the time. Whereas, variables starting with the symbol "@" can contain multiple values and are called *array* or *list*. A scalar variable can contain numbers that in Perl are classified in integer and floating-point numbers. Integers are whole numbers such as: "5, -9, 78" (without decimal part). Instead, floating points numbers has a decimal part, for example: "0.1, -0.12344" and so on. To put data into a variable, programmers have to use the assignment operator "=". An *array* or *list* is a variable that may holds zero or more primitive values. The elements stored in arrays and lists are numbered starting with zero, ranging from zero to the number of elements minus one. [Code 3.1](#) conveys a simple example of using the array variable.

```
#!/usr/bin/perl
# @Author Perl
# @Created Mar 29, 2017 3:30:48 PM
use warnings;
$@age=(25, 30, 44);
@names=("Joseph", "AnnaMary", "Bob");
$firstElem=$age[0];
print("$firstElem");
}
```

Code 3.1: An simple example to assign the first element of an array to a variable.

To modify the content of a variable is mandatory to use the assignment operator. For example, \$num=12345, we defined a variable called "num" and assigned to it the value "12345", the content of num will successively modify assigning new value \$num=1.3; for example. In addition to the numbers, Perl allows to variables to contain *strings*. A string is a series of characters surrounded by quotation marks such as "Hello World". Strings contain ASCII characters and escape sequences such as the \n of the example, and there is no limitation on the maximum number of characters composing a Perl string. Perl provides programmers mechanisms called 'escape sequences' as an alternative way of getting all the *UTF8* characters as well as the *ASCII* characters that are not on the keyboard. A short list of escape sequence is presented in [Table 1](#).

There is another type of string obtained by using single-quotes: ". The difference between single and double quotes is that no processing is done within single quoted strings, that is variable names inside double-quoted strings are replaced by their contents, whereas single-quoted strings treat them as ordinary text. To better explain the differences between single and double quotes consider [Code 3.2](#) as example:

Table 1 Escape characters

Escape sequence	Function
\t	Tab
\n	New line
\b	Backspace
\a	Alarm

```
#!/usr/bin/perl
# @Author Perl
# @Created Mar 29, 2017 3:30:48 PM
use warnings;
print '\t This is a single quoted string.\n';
print " \t This is a double quoted string.\n";
}
```

Code 3.2: Difference between the use of single and double quotes.

The differences between the double-quoted and the single-quoted string are that: the first one has its escape sequences processed, and the second one not. The output obtained is depicted in [Code 3.3](#):

```
#Console Output
\t This is a single quoted string.\n
This is a double quoted string.
```

Code 3.3: The difference of output due to the use of single and double-quotes.

This operation is called escaping, or more commonly, *backwhacking* allows programmers to put special character such as backslash into a string as conveyed in [Code 3.4](#), printing it on the screen in the correct format, let see [Code 3.5](#).

```
#!/usr/bin/perl
# @Author Perl
# @Created Mar 29, 2017 3:30:48 PM
use warnings;
print 'C:\WINNT\Profiles\'.'.\n';
print "C:\\WINNT\\Profiles\\.\n";
}
```

Code 3.4: Combination of escaping character to print in output the special character \.

```
#Console Output
C:\WINNT\Profiles\
C:\\WINNT\\Profiles\\
```

Code 3.5: Output result using single and double-quotes respectively.

Perl besides to allow users to define numbers and strings, it provides operators and functions to deal with numbers and strings.

Arithmetic Operators

The *arithmetic operators* comprise the basic mathematics operators like adding, subtracting, multiplying, dividing, exponentiation and so on. As appear for mathematics each operator comes with a precedence, which establishes the order in which Perl performs operations. Multiply and divide have a higher precedence than adding and subtract, and so they get performed first. To coerce Perl to perform operations with low priority first, it is mandatory to use brackets, for example, the following operation $1 + 2 * 3$ will

produce as a result 7. To obtain 9, as a result, it is necessary to rewrite the expression by using brackets in this way $(1 + 2) * 3$. Other arithmetics operators are *exponentiation operator* `**` and *module* `%`. Where module operator has the same precedence as multiple and divide, whereas exponentiation operator has higher precedence than multiple and divide, but lower precedence than minus operator.

Bitwise Operators

Bitwise operators work on bits since computer represent the complete information using bits. Bitwise operators perform bit by bit operations, from right to left. Where the rightmost bit is called the 'least significant bit,' and the leftmost is called the 'most significant bit'. Given two numbers 9 and 5 that in binary using 4 bits are expressed as $9 = 1001$, and $5 = 0101$ let see, which are the bitwise operators available in Perl. Bitwise operators include: the *and* operator and is written `&` in Perl. The `&` operator compares pairs of bits, as follows: if bits are both 1 the `&` gives 1 as a result, otherwise if one of the bits or both is equal to 0 the `&` gives 0 as a result. For example, the result of $9 \& 5$ is: $\$a \& \$b = 0001$. The *or* operator in Perl is `|`, where 0|0 is always 0 whereas, 1|1 and 1|0 is always 1 (independently of the left-right operator values). The result of $9|5 = 1101$. To know if one bit or both bits are equals to 1 it is possible to use the *exclusive-or* operator `^`, the result of $5 \wedge 9$ is 1100. Finally, by using the *not operator* `~` it is possible to replace the value from 1 to 0 and vice versa, for example, ~ 5 is 1010.

Equality Operators

Perl provides users operators able to compare equality of numbers and strings.

Comparing numbers

The equality operator `==` checks if the value of two numerical operands are equal or not, if are equal the condition gives *true* as result *false* otherwise. In Perl *true* is represented as 1 and *false* as 0. The Inequality operator, `!=`, verifies if two operands are different, if left value and right value are different the condition becomes true ($5 \neq 9$ gives as result *true*). The compare operator `<=>` checks if two operands are equal or not providing as result `-1`, `0` or `1` if the left operand is numerically less than, equal to, or greater than the second operand. Finally, the operators `<`, `<=`, `>` and `>=`. The `<` operator give *true* if the left operand is less than the right operand (e.g., $5 < 9$ gives as a result *true*). The `<=` operator gives *true* if the left operand is less or equal than the right operand (e.g., $5 <= 5$ gives as result *true*). The `>` operator give *true* if the left operand is greater than the right operand (e.g., $5 > 9$ gives as a result *false*). Finally, The `>=` operator give *true* if the left operand is greater or equal than the right operand (e.g., $9 >= 5$ gives as a result *true*).

Comparing strings

To compare two strings in Perl is necessary to use the comparison operators `cmp`. `cmp` compares the strings alphabetically. `cmp` returns `-1`, `0`, or `1` depending on whether the left argument is less, equal to, or greater than the right argument. For example, "Bravo" comes after "Add", thus `("Bravo" cmp "Add")` gives as result `-1`. To test whether one string is less than another, use `lt`. Greater than becomes `gt`, equal to is `eq`, and not equal becomes `ne`. There are also the operators *greater than or equal* to referred to as `ge` and *less than or equal* to referred to as `le`.

Logical operators

Logical operators make possible to evaluate the truth or falsehood of some statements at the time. The logical operators supported by Perl are *and* referred to as `&&`. The `&&` operator evaluates the condition and if both the operands are *true* returns *true* as result, *false* otherwise. The *or* referred to as `||` evaluates the condition, returning *true* if at least one of the operands is *true*, *false* otherwise. Not operand `!` is used to negate the logical state of the condition. As an alternative it is possible to use logical operators through the easier to read versions, *and*, *or*, and *not*.

Other operators

Other useful operators available in Perl are: string concatenation `.` given two string `$a = "abc"` and `$b = "def"` `$a.$b` gives as result `"abcdef"`. Repetition operator `x` gives in output the left operand repeated *x*-times, for example `(print "ciao"x3)`, will print `"ciaociaociao"`. Range operator `..`, return a list of value starting from the left value to the right value included. For example `(2..6)`, will return the following values `(2,3,4,5,6)`. Finally, the auto-increment `++` and auto-decrement `--` operator, that increases and decreases integer value by one respectively.

Conditional Statement

The *if-else* statement is the fundamental control statement that allows Perl to make decisions executing statements conditionally. The simplest conditional statement in Perl has the form:

```
if(<condition>){<Statement 1>;<Statement 2>;...};
```

The if-else statement has an associated expression and statement. If the expression evaluates to true, the interpreter executes the statement. If the expression evaluates to false the interpreter skips the statement. An example of using if statement is presented in [Code 3.6](#).

```
#!/usr/bin/perl
# @Author Perl
# @Created Mar 29, 2017 3:30:48 PM
use warnings;
if ($a >= $b){
    print ( 'The values of $a and $b is : ' . ($a) );
}
```

Code 3.6: An example illustrating a basic use of the if statement.

An if statement can include an optional `else` keyword. In this form of the statement, the expression is evaluated, and, if it is true, the first statement is executed. Otherwise, the second statement (`else`) is executed. The more general conditional in Perl presents the form:

```
if(<condition>){StatementsBlock1}; else{StatementsBlock2};
```

```
#!/usr/bin/perl
# @Author Perl
# @Created Mar 29, 2017 3:30:48 PM
use warnings;
if ($a>$b){
    print ( '$a is greater than $b' . ($a->$b) );
} else {
    print ($b is greater than $a' . ($b->$a) );
}
```

Code 3.7: An example of if else statement.

When you use nested if/else statements, some caution is required to ensure that the else clause goes with the appropriate if statement. Nesting more than one condition could be difficult to read. Thus Perl provides to programmers the if `elsif` statement, which presents an easier to read form:

```
if ( < condition1 > ) < action > elsif ( < condition2 > ) < secondaction >
    elsif ( < condition3 > ) ... else <if all elsif fails>
```

Code 3.8: An example of if elsif statement:

Loops

The loops statement are the basic statement that allows Perl to perform repetitive actions. Perl programming language provides specific types of loop.

while loop that only executes the statement or group of statements only if the given condition is *true*. The general form of *while* loop is:

```
while (<condition>){<block of statements>}
```

Code 3.9 illustrates the of while loop.

```
#!/usr/bin/perl
# @Author Perl
# @Created Mar 29, 2017 3:30:48 PM
use warnings;
use strict;
#initialisation of $a to 0
$a = 0;
# while loop execution
while($a<=9){
    printf "Value_of_a: %d\n";
    $a = $a + 1;
}
```

Code 3.9: An example of while loop that prints the numbers from 0 to 9.

until loop execute a statement or a group of statements till the given condition not becomes true. The general form of until loop is:

```
until (<condition>){<block of statements>}
```

Code 3.10 presents a simple use case of until loop.

```
#!/usr/bin/perl
# @Author Perl
# @Created Mar 29, 2017 3:30:48 PM
use warnings;
use strict;
#initialisation of $a to 0
$a = 0;
# until loop execution
until($a==10){
    printf "Value_of_a: %d\n";
    $a++;
}
```

Code 3.10: An example of until loop that prints the numbers from 0 to 9.

do loop is very similar to the while loop, except that the loop expression is tested at the bottom of the loop rather than at the top. do ensures that the body of the loop is executed at least once. The syntax of do loop looks like:

```
do{<block of statements>}while(<condition>)
```

The for loop executes the statements in a block a determinate number of times. The for in is more general form is:

```
for (init; condition; increment){Block of statements; }
```

The `for` iterates on each element in an array as well as in a list as conveyed. As [Code 3.11](#) shows the use of `for` loop to print the elements of an array.

```
#!/usr/bin/perl
# @Author Perl
# @Created Mar 29, 2017 3:30:48 PM
use warnings;
use strict;
my @array = (1,2,4,3);
my $i;
# for loop
for $i (@array){
    printf "\n_$i";
}
```

Code 3.11: An example of `for` loop that prints the values of an array.

It is possible to use `foreach` and `for` loop indistinctly on any type of list. It is worthy to note that the both loops create an alias, rather than a value. Thus, any changes made to the iterator variable, whether it be `$` or one you supply, will be reflected in the original array. For instance:

```
#!/usr/bin/perl
# @Author Perl
# @Created Mar 29, 2017 3:30:48 PM
use warnings;
use strict;
# create an array of ten elements
my @array = (1..10);
foreach (@array) {$_++;}
print "Array is now: _@array\n";
```

Code 3.12: `foreach` loop that prints and modify the values of the array:

The code in [Example 3.12](#) will change the contents of the array, as follows:

Array is now: 2 3 4 5 6 7 8 9 10 11

Fibonacci Sequence Example

In this section, will be introduced the algorithm wrote in Perl to compute the Fibonacci sequence. The Fibonacci sequence is a recursive formulation where each element is equal to the sum of the first two. This sequence owes its name to the Italian mathematician Fibonacci. The purpose of the sequence was to identify a mathematical law to describe the growth of a population of rabbits. The [Code 3.13](#) shows the computation of the Fibonacci's sequence through Perl programming language.

```
#!/usr/bin/perl
# @File Fibonacci.pl
# @Author Perl
# @Created Mar 29, 2017 3:30:48 PM

use strict;
use warnings;

my $f1 = 0;
my $f2 = 1;

printf "\nHow many numbers of the Fibonacci's sequence
would you display?\n";
#We use <STDIN> library to get the data from stdin here
my $n = <STDIN>;
for (my $i=0;$i<$n;$i++){
    printf "%d\n", $f1;
    my $sum = $f1 + $f2;
    $f1 = $f2;
    $f2 = $sum;
}
```

Code 3.13: A simple script example to compute the Fibonacci's Sequence.

Closing Remarks

Perl first appeared in 1987 as a scripting language for system administration, but thanks to its very active community became a very powerful, flexibility and versatility programming language. The main strength of Perl's popularity is the Comprehensive Perl Archive Network (CPAN) library, that is very extensive and exhaustive collection of open source Perl code, ranging from Oracle to iPod to CSV and Excel file reader as well as thousands of pages of Perl's core documentation. Thus, Perl exploiting the knowledge and experience of the global Perl community, it provides help to everyone to write code, bug resolution and code maintenance. In summary, the key points of Perl are (i) management of Regular Expressions are natively handled through the regular expression engine. Regular expression engine is a built-in text process that, interpreting patterns and applying them to match or modify text, without requiring any additional module. (ii) The flexibility, Perl provides programmers only three basic variable types: Scalars, Arrays, and Hashes. That's it. Perl independently figures it out what kind of data developers are using (int, byte, string) avoiding memory leaks. Finally, (iii) the portability. Perl works well on several operating systems such as UNIX, Windows, Linux OSX, as well as on the web.

Introduction

Computational analysis is becoming an essential part of the modern biological research, to speed up the data analysis. This change is due to the high throughput methodologies (Abu-Jamous *et al.*, 2015) that are producing an enormous amount of data for each single experiment, requiring techniques able to analyze as much as possible information in the short possible time avoiding that become useless (Marx, 2013). The high-throughput methods comprise Protein Chips, Mass Spectrometry (for identification and quantification (LC-MS)), Yeast Two-Hybrid (that are techniques for investigating physical interactions among proteins), and Surface Plasmon Resonance technologies for studying Kinetic Dynamics in proteins. As well as, high-throughput sequencing includes Next Generation Sequencing (NGS), RNA sequencing, lipid profiling by GC-MS. Many computer software tools exist to perform biological data analyses, requiring the integration of several disciplines such as biology, physics, mathematics, computers science, statistics, engineering known as bioinformatics. These huge amount of data require a lot effort from computer scientists to face from several different points of view, from data storage (Barrett *et al.*, 2009) perspective where, there are a lot of public databases such as GenBank (Benson *et al.*, 2013), Protein Data Bank (PDB) (Bank, 1971), IID (Kotlyar *et al.*, 2015) Reactome (Joshi-Tope *et al.*, 2005), Panther (Mi *et al.*, 2005) and so on, that have been growing exponentially, in the last decade. As well as, computer scientist have to develop efficient tools and algorithm able to deal with this huge amount of data in the short possible time providing life science researchers practical tools able to simplifying their work (Guzzi *et al.*, 2014; Milano *et al.*, 2016; Agapito *et al.*, 2013a). Flanked to the data analysis, there is data visualization that makes it possible to highlight to the researcher's information not visible otherwise, especially reading strings or worst numbers (Pastrello *et al.*, 2013; Agapito *et al.*, 2013b). As a result, computer-science now play a more crucial role in the advancement into the life science research.

An example to demonstrate the power of bioinformatics to analyze a biological problem simple or complex. Let suppose that a research group discovers a fascinating segment of monkey's DNA from which could be possible extract some clue to explain the development of malignant brain neoplasms in humans. After DNA sequencing, researchers have to perform a search in public and private sequence databases and other data sources by using sequence alignment tools (i.e., BLAST) to get some match with known sequences. Although researcher will find some related sequences, this does not means that exist a link that could explain how brain neoplasms develop in human. To get this information, it is necessary to quotidianly query databases, task that could take several hours, days or worse months. Fortunately, bioinformatics propose several software tools, libraries that simplify the writing of a program, that in the previous example automatically conducts a daily BLAST search of databases for match with the new DNA sequence.

To help life science scientists several initiatives were born to simplify the analysis of life science area, including the BioPerl library (Stajich *et al.*, 2002).

The BioPerl is an international project involving several users and developers in the overall world of open source Perl tools for bioinformatics, genomics, and life science. BioPerl project is managed by the *Open Bioinformatics Foundation* (OBF) a non-profit, volunteer-run group devoted to promoting the Open Source software development and Open Science within the biological research community for more information visit the <http://BioPerl.org/index.html> web-site. The OBF foundation as well as BioPerl manages other open source projects including *BioJava*, *Biopython*, *BioRuby*, *BioSQL*, *DAS* (and related list of Global Sequence Identifiers), *MOBY*, *EMBOSS* and *OBDA*.

At the time of writing on CPAN at the following web-site <https://metacpan.org/release/BioPerl> and Github <https://github.com/BioPerl/BioPerl-live/releases/tag/release-1-7-0> is available the release of BioPerl v1.7.0, to reduce the number of dependencies required during the installation process as well as reducing the overhead maintenance process. In short, Bioperl is a set of Perl packages that promote the development of Perl scripts for bioinformatics applications.

BioPerl Installation

The BioPerl modules are distributed as a tar file that expands into a standard perl CPAN distribution. To install BioPerl on your Unix, Linux or MacOSX computer follow the instructions below.

Installing BioPerl on Linux and Mac OSX Machines

To install BioPerl on Linux, is preferred to use the repository, since many Linux distributions have already packaged BioPerl. Installing BioPerl from repository should be preferred since avoid to install out of date versions. Before proceeding with the

installation make sure that on your system is installed the release of BioPerl version 5.8 or higher, and make command (for the Mac OS system the make is not installed, and requires to install Xcode Developer Tools). BioPerl could be installed through CPAN or Github. The installation steps to install BioPerl from CPAN are the following: To test if on your system is already installed *cpan* alias, write from the command line the *cpan* command and press *enter*. If *cpan* is installed on your screen should be appear the following message: CPAN.pm requires configuration, but most of it can be done automatically. If you answer 'no'

below, you will enter an interactive dialog for each configuration option instead. Would you like to configure as much as possible automatically?

[yes]. After *cpan* is installed, it is necessary to find the latest BioPerl package entering the following command from the command line prompt: i) *cpan* and *enter*; ii) from the *cpan* terminal enter:

```
cpan> d /bioperl/ and enter; iii) will be displayed all the available version of BioPerl:
```

```
Distribution CDRAUG/Dist-Zilla-PluginBundle-BioPerl-0.25.tar.gz
```

```
Distribution CJFIELDS/BioPerl-1.007001.tar.gz
```

```
Distribution CJFIELDS/BioPerl-1.6.924.tar.gz
```

```
Distribution CJFIELDS/BioPerl-Network-1.006902.tar.gz
```

Finally, iv) install the most recent release in this case: *cpan> install CJFIELDS/BioPerl-1.007001.tar.gz*. Otherwise, to install BioPerl from Github the steps are the following: By the command line type the following command and press *enter*:

git clone https://github.com/bioperl/bioperl-live.git. After go to the folder *bioperl-live* through the command: *cd bioperl-live* and press *enter*.

More detailed and updated information about the installation can be retrieved at the following web address: <http://bioperl.org/INSTALL.html>.

Installing BioPerl on Windows Machines

In this section, we will illustrate how to Install Perl on Windows machines by using CPAN for Strawberry. Installing Bioperl from repository should be preferred since avoid to install out of date versions. Before proceeding with the installation make sure that on your computer is installed the release of BioPerl version 5.8 or higher, the accessory compiling program MinGW. MinGW provides tools such as *dmake* and *gcc*. MinGW has to be installed through the Perl Package Manager Index (PPM) available from the ActiveState PPM repository. In a command line window type: *C:\>ppm install MinGW* Be sure to choose the version of MinGW compatible with your ActivePerl version, because is ActivePerl is compatible only with a specific release of MinGW. To run CPAN shell into a command window, type the *cpan* command and press *enter*. As a result, the CPAN prompt will be displayed. At the *cpan>* prompt, typing the command "*cpan> install CPAN*" that will upgrade CPAN to the latest release. At the *cpan>* prompt, type *cpan> o conf prefer installer MB* to force CPAN to use Build.PL scripts for installation, and typing *cpan> o conf commit* to save the modify. Always from the CPAN prompt, type *cpan>install Module::Build* and press *enter*, *cpan>install Test::Harness* press *enter*, *cpan>install Test::Most*. Now it is possible to install BioPerl.

First install *local::lib* module by using the following command *perl -MCPAN -Mlocal::lib -e 'CPAN::install(LWP)'* more detailed information are available at <https://metacpan.org/pod/local::lib> web site. At the end of *local::lib* installation on your own machine, it is possible to install BioPerl using the following command: *perl -MCPAN -Mlocal::lib -e 'CPAN::install(LWP)'*.

More detailed and updated information about the installation can be retrieved at the following web address: <http://bioperl.org/INSTALL.WIN.html>.

Objects Management in Perl and BioPerl

Object-Oriented Programming (OOP for short) is the new paradigm that has supplanted the "structured," procedural programming techniques. BioPerl is entirely developed in Perl consequently it supports object-oriented programming as well as, procedural programming. OOP springs from the real world objects vision, extending it to the computer programs. In OOP a program is made of objects, each one with particular properties and operations that the objects can perform. In OOP, programmers have to only care about what the objects expose (the public methods). So, just as a television manufacturers don't care about the internals components of a power supply, most OOP programmers do not bother how an object is implemented. Structured programs consist of a set of procedures (or methods) to solve a problem. The first step regards the developing of the procedures, whereas only at the last step it is required to find appropriate ways to store the data. Conversely, OOP reverses the order putting data first and then looks at the methodologies that operate on the data. The key point in OOP is to make each object responsible for carrying out a set of related tasks. If an object relies on a job that isn't its responsibility, it needs to have access to another object whose responsibilities include that function. Information hiding in OOP is known as data encapsulation. Data encapsulation maximize reusability, reducing dependencies, and minimize the debugging time. Further, as good practice of OOP programming, an object should never directly manipulate the internal data of other objects, as well as should not it expose data for other objects

to access directly. An object or class in Perl and consequently in BioPerl is simple a package with subroutines that function as methods, modifying the object's state. In particular object's methods are the behaviour of an object (can a programmer can apply to it), and internal data (the fields) are the object's state this is, how the object reacts when those methods are applied to it. An example of class in BioPerl is presented in [Code 3.1](#).

```
#!/usr/bin/perl
# @Author Perl
package Lion;
sub roar {
    ....
}
sub manedColor {
    ....
}
```

Code 3.1: A simple example of Class in BioPerl.

To initiates an object from a class, is it mandatory to use the new method, and to use the methods provided by an object, has to be used the "`->`" operator, as shown in [Code 3.2](#).

```
#!/usr/bin/perl
# @Author Perl
...
$simba = new Lion;
...
print $simba->roar();
...
print "Simba's maned_color is : ". $simba->manedColor();
...
```

Code 3.2: A simple example of Object instantiation in BioPerl.

A Perl module is a reusable package enclosed into a library of files, whose name is the same of the package name. Each Perl module has a unique name. Moreover, Perl provides a hierarchical namespace for modules, to minimize namespace collision. Components of a module name are separated by double colons (`::`), for example, `Math::Complex`, `Math::Approx`, `String::BitCount` and `String::Approx`. Each module is contained in a single file, and all module files have `.pm` as an extension. To have a hierarchy in the name of the modules, Perl allow to stores files in subdirectories. A module can be loaded into any script by calling the `use` function, as conveyed from the [Code 3.3](#).

```
#!/usr/bin/perl
# @Author Perl

use Math::Trig;

$x = tan(0.9);
$y = acos(3.7);
$z = asin(2.4);

$rad = deg2rad(120);
# Import constants pi
use Math::Trig 'pi';
```

Code 3.3: A simple example of Module loading through the command use in BioPerl.

BioPerl Modules

BioPerl provide software modules for several of the typical activities to the analysis of life science data, including:

Sequence Objects

Bio::Seq is the main sequence object in BioPerl. A Seq object is a sequence and it contains a Bio::PrimarySeq object and annotations associated to the sequence. Seq objects can be created explicitly when needed through the new command, or implicitly by reading file containing sequences data by using the Bio::SeqIO object. PrimarySeq is the essential version of Seq object. PrimarySeq contains merely the sequence data itself and some identifiers (id, accession number, molecule type = DNA, RNA, or protein). Using PrimarySeq object can significantly speed-up the program execution and decrease the amount of central memory that the program requires to handle large sequences. Biological sequence's starting and ending points are represented in BioPerl by the Bio::LocatableSeq that is a Bio::PrimarySeq object able to represent the start and end points of any sequence, loaded manually. To handle very large sequences (i.e., greater than 100 MBases) BioPerl defines the LargeSeq object that is a special object of Seq type, with the capability to store very large sequences into the file system avoiding out of memory.

Alignment Objects

Conversely for the sequence handling, BioPerl provide only two modules to align sequences that are Bio::SimpleAlign and Bio::UnivAln. Multiple sequence alignment (MSA) in BioPerl are managed by the Bio::SimpleAlign object. The SimpleAlign objects allow aligning sequence with different length, providing a set of built-in manipulations and methods for reading and writing alignments. In the more recent versions of BioPerl, the use of Bio::UnivAln is not recommended. As good programming practice, the alignments have to be generally handled by using the SimpleAlign module where it is possible.

Illustrative Examples

In this section, will be presented some use case of BioPerl modules to accomplish any standard bioinformatics' task, by means of simple example codes. A way to manipulate sequences with BioPerl can be accomplished by using the Bio::Seq module. By default, the Bio::Seq module contains a sequence and a set of sequence features aggregate with its annotations. [Code 5.1](#) is a simple complete BioPerl script that demonstrate how to directly assign a sequence and related additional information to a BioPerl object.

```
#!/usr/bin/perl
# @Author Perl

use Bio::Seq;

$seq = Bio::Seq->new(-seq => 'agtagtagcagtagagct',
                    -desc => 'Simple_Bio::Seq_object',
                    -display_id => 'sequence',
                    -accession_number$
                    -alphabet => 'dna' );

print($seq->seq()."\n");
```

Code 5.1: The script is an example that demonstrates how to use Seq object to manually create a sequence and handling with the sequence, through the available methods.

Let's examine in details the script presented in [Code 5.1](#). The first line `#!/usr/bin/perl` is called interpreter directive (also called "shebang"), specifying to the operating system the suitable interpreter to execute the script. Second line contains a comment, whereas line 4 import the *Seq Bioperl* module. To create and initialize a Seq object it is mandatory to use `new` command (let see row 5 in [Code 5.1](#)). The `$seq` object is manually initialized by using the following commands: `seq` that sets the sequence to be handled, `-desc` that sets the description of the sequence, `display id` sets the *display id*, also known as the name of the Seq object to visualize, `accession number` sets the unique biological id for a sequence, commonly called the accession number. For sequences from established databases, should be used the accession number provided by the database curator. Alphabet the possible values is one of *dna*, *rna*, or *protein*, if the value is not provided will be automatically inferred.

However, in most cases, it is more indicate to access sequence data from some online data databases. BioPerl allowing users to access remote database among which: *Genbank*, *Genpept*, *RefSeq*, *Swissprot*, *EMBL*, *Ace*, *SWALL*, *Reactome* and so on. Accessing sequence data from the principal biological databases is straightforward in BioPerl. Data can be obtained employing the sequence's accession code (i.e., "`seq2 = gb -> get Seq by acc('AH012836');`" or open a stream on multiple sequences (i.e., "`seqio = gb -> get Stream by id(['AH012836','BA000005','AH011052']);`"). GenBank data can be retrieved by using the code proposed in [Code 5.2](#) for example.

```
#!/usr/bin/perl

$ENV{'PERLLWP_SSL_VERIFY_HOSTNAME'} = 0;

use Bio::DB::GenBank;

$gb = new Bio::DB::GenBank();
# this returns a Seq object from genbank:
$seq = $gb->get_Seq_by_id('AH012836');
print($seq->display_id()."\n". $seq->length()."\n");
print($seq->seq()."\n");
```

Code 5.2: Shows the code to get data of a particular sequence (AH012836 is the accession code of *Sus scrofa* organism) from GenBank that will be used to initialize an Seq object.

Let's examine in details the script presented in [Code 5.2](#). The first line `#!/usr/bin/perl` is called interpreter directive (also called "shebang"), specifying to the operating system the suitable interpreter to execute the script. The second line contains the definition of an environment variable. The definition of this variable is mandatory because, otherwise perl throws an exception like: "Can't verify SSL peers without knowing which Certificate Authorities to trust".

To disable verification of SSL peers set the PERL LWP SSL VERIFY HOSTNAME environment variable to 0. Line 5 create a new object suitable to contain data from GenBank, through the `new` command. Line 6 contains a comment, line 7 is the code used to

retrieve data from genbank, related to the organism identified by means of the *AH012836* value. Finally, lines 8, 9 print on screen the sequence identifier, the sequence length and the sequence as a string of letters. In addition to the methods directly available in the Seq object, BioPerl provides the Bio::Tools::SeqStats objects to compute simple statistical and numerical properties of the primary sequence. [Code 5.3](#) presents an case use of the Bio::Tools::SeqStat object, to compute the molecular weight of a sequence as well as the counts of each type of monomer (i.e., amino or nucleic acid).

```
#!/usr/bin/perl
$ENV{'PERLLWP_SSL_VERIFY_HOSTNAME'} = 0;
use Bio::DB::GenBank;
use Bio::Tools::SeqStats;

$gb = new Bio::DB::GenBank();
# this returns a Seq object :
$seq = $gb->get_Seq_by_id('AH012836');#('MUSIGHBA1');
print($seq->display_id()."\n".$seq->length."\n");
print($seq->seq()."\n");
$translation = $seq->translate;
#print($translation);

$weight = Bio::Tools::SeqStats->get_mol_wt($seq);
print "\nMolecular_weight_of_the_primary_sequence",
      $seq->id()."_is_between". $$weight[0]."_and".
      $$weight[1]."\n";

$hash_ref = Bio::Tools::SeqStats->count_monomers($seq);
foreach $base (sort keys %$hash_ref) {
    print "Number_of_bases_of_type". $base. "=".
          %$hash_ref->{$base}."\n";
}
```

Code 5.3: Shows the code to compute some analysis and statistic on the primary sequence.

Let's analyze in details the script presented in [Code 5.3](#). Line 14 declare and initialize the *weight* variable to contain a reference to the *SeqStats* object.

from the *seq* variable. In line 15 print the molecular weight of the primary sequence referred from the *seq* variable. Since the sequence may contain ambiguous monomers, the molecular weight is returned as range. Line 19 define an hash containing the count of each type of amino acid contained in the *seq* sequence. The cycle in line 20 allow to scan all the hash to get each amino acid and print its own occurrence in the sequence. Another common difficult and error prone bioinformatics task is manually converting sequence data among the several available data format. BioPerl Bio::SeqIO object can read as input several different file formats among which: Fasta, EMBL, GenBank, Swissprot, PIR, GCG, SCF, phd/phred, Ace, fastq, exp, or raw (plain sequence), and converting in another format and written to another file. The [Code 5.4](#) shows, how read a file from a directory on your computer in a format and convert it in another format.

```
#!/usr/bin/perl
use Bio::SeqIO;
$input = Bio::SeqIO->new(-file => "./GLA_prot.fasta",
                        -format => 'Fasta');
$output = Bio::SeqIO->new(-file => ">pfamFromat.pfam",
                        -format => 'EMBL');
while(my $seq=$input->next_seq()){
    $output->write_seq($seq);
}
print ("Conversion_job_ended!!!\n");
```

Code 5.4: Shows the how to convert an input file in FASTA format in EMBL format.

Analyzing in detail [Code 5.4](#), the statement in lines 3 and 4 allow to define the location on the disk where is stored the fasta file (the input file to convert) in particular, the parameter `-f => "name input file"` allow to the perl interpreter to load the file, whereas the parameter `-format => 'Fasta'` allow to specify to the interpreter the format of the input file. The statement wrote in lines 5 and 6 define the name and the location on the disk where to write the converted file `-file => ">pfamFromat.pfam"` and the new format `-format => 'EMBL'`. Block statement in line 7 allow to fetch a sequence at time (`$seq=$input->next_seq()`) until there are some, writing in output through the statement `"$output->write_seq($seq);"`.

Computing Languages for Bioinformatics: Python

Pietro H Guzzi, University “Magna Graecia” of Catanzaro, Catanzaro, Italy

© 2019 Elsevier Inc. All rights reserved.

Introduction

A concise description of Python is given by the Zen of Python that is available by typing `import this` on the Python console (Van Rossum *et al.*, 2007).

```
Beautiful is better than ugly.
Explicit is better than implicit.
Simple is better than complex.
Complex is better than complicated.
Flat is better than nested.
Sparse is better than dense.
Readability counts.
Special cases aren't special enough to break the rules.
Although practicality beats purity.
Errors should never pass silently.
Unless explicitly silenced.
In the face of ambiguity, refuse the temptation to guess.
There should be one – and preferably only one – obvious way to do it.
Although that way may not be obvious at first unless you're Dutch. Now is better than never.
Although never is often better than *right* now.
If the implementation is hard to explain, it's a bad idea.
If the implementation is easy to explain, it may be a good idea.
Namespaces are one honking great idea – let's do more of those!
```

As a consequence Python is a highly readable language avoiding, for instance, the use of curly brackets to delimit blocks and the optional use of semicolons after statements. Blocks in Python are delimited by white space indentation: the increase in indentation delimited the start of statements while the decrease signifies the end of the current block (off-side rule). Moreover colons (:) are used to signal the start of the statement. For instance, following code shows the indentation used to represent the code of a sub-procedure (Zelle, 2004).

```
def hello():
    print('Hello World')
hello()
```

The simple program contains the definition of the subprocedure `hello()` and the subsequent invocation of the subprocedure.

Main Statements of Python

Python statements are similar to other programming languages and includes (Cai *et al.*, 2005):

- The if statement, which conditionally executes a block of code, along with else and elif (that stands for else-if);
- The while statement which conditionally executes a cycle;
- The for statement which executes a loop (using both iterators (for x in set) and indices (for x in range)).
- The try statement used to present code blocks that may raise exceptions to be caught and handled by except clauses; differently to other languages it also ensures that a finally block will always be run;
- The class statement used to define a class in object-oriented programming;
- The def statement, which defines a function or method;
- The import statement used to import external modules in a program.

Data Structures in Python

Python implements main data types such as int for integers, long for long integers, float for floating point numbers and bool for boolean. Moreover, it has some simple data structures in the standard library:

Tuple: Tuples are used to merge into a single structure multiple variables or objects. Tuples are immutable and are defined by specifying items separated by commas within an optional pair of parentheses. For instance the statement `t=(a,b,c)` creates a tuple, identified by `t`, containing `a`, `b`, and `c` objects. Tuples cannot be accessed by referencing the position. Following statements create two tuples and print their content.

```
b = ("one",)
```

```
# Two-element tuple.  
c = ("one", "two")  
if "one" is in c:  
    print("ok")  
# the statement print ok
```

Lists: A list is an ordered and indexed collection of heterogeneous object. Lists are created by using square brackets, e.g., `l=[]` or the `list()` statement i.e. `l=list()`. List are mutable and they may be accessed using indexes, e.g., `l[index]` or iterators e.g., `for x in l`. Python also offers main function for list operations, e.g., `append`, `delete`, `search`. Following statements create a list, put into the list 4 elements and finally write each element to the screen.

```
# creation of the list  
l=list()  
# Insertion of the elements into the list  
l.append(1)  
l.append(2)  
l.append('a')  
l.append('b')  
# print of the elements  
for x in l: print(x)
```

Sets. A set is an unordered list of objects in which each object compares once. Sets are created by using curly brackets e.g., `s=`. Python offers many functions to testing for membership, to test whether it is a subset of another set, to find the intersection between two sets.

```
# creation of the sets  
s1=set()  
s2=set()  
# Insertion of the elements into the sets  
s1.add(2)  
s1.add(4)  
s2.add(2)  
s2.add(4)  
s2.add(5)  
print(s1.intersection(s2))  
# Output: 2,4  
print(s1.union(s2))  
# Output: 2,4,5
```

Dictionaries: A dictionary is a ordered collection of key: values pair. Note that the key must be unique. It is mandatory to use only immutable objects (like strings) for the keys of a dictionary, while but you can use either immutable or mutable object for the values of the dictionary. Pairs of keys and values are specified by using the notation `dict = key1: value1, key2: value2`. Key-value pairs are separated by a colon, and the pairs are separated commas.

```
items = {'john': 4098, 'sean': 4139}  
items['guido'] = 4127  
print(items)  
Output: {'sean': 4139, 'guido': 4127, 'john': 4098}  
print(items['john'])  
Output: 4098  
del (items['sean'])  
items['irv'] = 4127  
print(items)  
{'guido': 4127, 'irv': 4127, 'john': 4098}  
print(items.keys())  
Output: ['guido', 'irv', 'john']  
'guido' in tel  
Output: True
```

Definition of Functions in Python

A function is a set of statement organised to perform a single, related action to provide modularity and code reusing.

Functions are defined using the keyword `def` followed by the function name and parentheses(`()`). Any input parameters or arguments should be placed within these parentheses. The first statement of a function may be a documentation string of the function

(or docstring). The code block within every function is indented and the end of the function is the end of the indentation or the state `return[expression]` that exits a function, optionally passing back an expression to the caller.

```
# definition of a function

# def triplicate(a):
# body of the function
#     return 3*a
# return statement
# use of the function

a=triplicate(3)
print(a)
Output: 9

def printinfo(name, age):
    "This prints a passed info into this function"
    print "Name: ", name
    print "Age ", age
    return;

# Now you can call printinfo function
printinfo(age=50, name="miki")
```

Object Oriented Programming in Python

Object-Oriented Programming in Python is substantially different from classical OOP languages like Java. The definition of a class in Python starts with the `class` command followed by a set of statements. Python does not admit the explicit definition of attributes, and they are defined as the `__init__()` function that also acts as a constructor. Moreover, attributes may also be added during the use of the object. Therefore two objects of the same class may have different attributes. Finally, Python does not admit an explicit definition of public and private functions. Private functions are defined as `__function(self)`, but their meaning is quite different from other languages like Java. Multiple inheritances is not admitted and interface cannot be defined. For instance, the simple definition of a `Point` class, storing the `x` and `y` coordinates of a point in a two-dimensional plane is the following.

```
class Point:
    def __init__(self, x, y):
        self.x = x
        self.y = y
    def getCoordinates(self):
        return self.x, self.y
```

The point has two attributes `x`, and `y` and the class have two functions, the constructor and the methods `getCoordinates`. The function called `__init__` is run when we create an instance of `Point`. The `self` keywords are similar to this keyword in java since it references to the implicit object. All the class methods need to use `self` as the first parameter, but during the use, the parameter (`self`) is omitted, thus one may invoke class methods, as usual, using the `(.)` style. `self` is the first parameter in any function defined inside a class. To access these functions and variables elsewhere inside the class, their name must be preceded with `self` and a full-stop (e.g., `name.method`).

Bioinformatics and Data Science in Python

Recently, data science has become a large field and its application in bioinformatics, in computational biology and in biomedicine are very popular. Data science, following a common accepted definition, is a novel field in which statistics, data analysis and computer science are mixed together to extract knowledge or insights from data. In particular, from computer science, data analysis uses methods and tools from machine learning, data mining, databases, and data visualisation. Python is largely used in data science, therefore we will present some project that offer useful libraries for data science in Python.

Among the others, one motivation for the use of Python in data science, is the possibility to easily distribute libraries through the community. Python community has developed some databases for distributing codes. Actually the Python Package Index (PyPI) is a freely available repository of softwares. PyPI offer the possibility for the developers to reach a big community and for the community to find and install packages and libraries. PyPI (see Relevant Websites section), that allows to users to find Python packages in various domains, including Bioinformatics and datascience. Using PyPI users may install libraries using a simple command from the prompt, in a similar way to `apt-get` for linux distributions.

Data Science Packages in Python: Scikit-Learn

Using the PyPI search engine for data science user may find more than 50 libraries for data science. One of the most popular libraries is sci-kit learn.

Scikit-learn includes implementations for various classification, regression and clustering algorithms. Implemented models span a large model including support vector machines, random forests, neural networks, and classical clustering algorithms like k-means and DBSCAN. It is based on Python numerical libraries and it easily interoperate with other libraries. Scikit-learn is largely written in Python, with some core algorithms written in Cython to achieve performance. Scikit-learn also offers a popular website that includes a large set of examples to learn the use of libraries. To install scikit-learn user may use pip and the command `pip install -U scikit-learn`.

Biopython

The Biopython Project (Cock *et al.*, 2009) is an association of developers that aim to develop tools for computational biology. Biopython is available for the user through the PyPI installers and through the web site <http://biopython.org>.

BioPython contains many classes for supporting researchers and practitioners in molecular biology. Using Biopython user may read biological sequences and annotations written in different file formats as well as he/she may interoperate with almost all the online databases of biological information. Biopython offer modules for sequence and structure alignment as well as some simply machine learning algorithms.

Pietro H. Guzzi is an assistant professor of Computer Science Engineering at the University Magna Grcia of Catanzaro, Italy. His research interests comprise semantic-based and network-based analysis of biological and clinical data.

Computing Languages for Bioinformatics: R

Marianna Milano, University of Catanzaro, Catanzaro, Italy

© 2019 Elsevier Inc. All rights reserved.

Introduction

R is a free software programming language and a software environment for statistical computing and graphics. The R language is widely used among the scientific community for developing statistical software and data analysis. It offers the widest range of available methodologies such as linear and nonlinear modeling, classical statistical tests, time-series analysis, classification, and clustering and graphical techniques for understanding data, from the most basic to the most complex. R is an open source project, and there are freely available command line interfaces or graphical front-ends for different platforms, including Windows, Mac OS X, and Linux. R is under constant development, with new updates added daily. In fact, R is supported by scientists and programmers who can help and advise the users. In the programming language field, R is an important tool for development in the numerical analysis and machine learning spaces. Due to the high-level of interpreted languages, such as R, the user can easily and quickly prototype new computational methods. R has become very popular, and is now being used for projects that require substantial software engineering, as well continuing to be used as an interactive environment for data analysis. Over the years, the R has become one of the most used tools for scientific computation. The reasons are related to the existence of a collection of comprehensive statistical algorithms, access to high-quality numerical routines, and integrated data visualization tools. A second strong motivation for using R is its ability to interoperate with many other languages. Algorithms that have been written in another language rarely need to be reimplemented for use in R. Typically, one need write only a small amount of interface code, and the routines can be accessed from within R. Finally, R supports the creation and use of self-describing data structures.

R is the programming language on which the Bioconductor Project ([Reimers and Carey, 2006](#)) is founded. The goal of Bioconductor is the creation of extensible software for computational biology and bioinformatics. Most Bioconductor components are distributed as R packages. The Bioconductor project provides R packages for the analysis of genomic data, such cDNA microarrays, object-oriented data-handling, and for analysis of data from next-generation high-throughput sequencing methods.

R Environment

R is an integrated suite of software that enables calculation, data manipulation, and graphical display. In particular, R comprises an effective data handling and storage facility, a suite of operators for calculations on arrays, an integrated collection of tools for data analysis, graphical facilities for data analysis and display, and is an effective programming language that includes conditionals, loops, user-defined functions, and input and output facilities.

Analysis and Assessment

R Package System

The R environment includes a well-established package system, together with related software components and documentation. The package system represents the heart of the R System. There are several hundred packages that enable a wide range of statistical analyses and visualization objectives. An R package typically consists of a collection of functions and data structures that are appropriate for solving a specific problem. Each R package folder contains the R code, help pages, data, vignette documentation (see below), code written in other languages such as C or FORTRAN, and files that describe how to install the package. Packages should run on all platforms supported by R. There are currently three main repositories for R packages: Bioconductor ([Reimers and Carey, 2006](#)), CRAN ([Claes et al., 2014](#)), and Omegahat ([Lang, 2000](#)). CRAN contains over 1000 R packages, while Bioconductor and Omegahat are smaller. Packages can be downloaded as open source. The package system ensures that software modules are developed and distributed with clearly defined standards of test-based validation, version identification, and package interdependency.

Object-Oriented Programming Support

Object-oriented programming (OOP) ([Rumbaugh et al., 1991](#)) has become widely used in software engineering. R currently supports two internal OOP systems: S3 and S4. S3 does not require the specification of classes, and there is control of objects and inheritance. The emphasis of the S3 system was on generic functions and polymorphism. S4 requires formal class definitions. In S4, classes are defined to have specific structures and inheritance relationships, and methods are defined both generically and specifically. S4 is better suited for developing large software projects but has an increased complexity of use.

World Wide Web Connectivity

R contains a set of functions and packages that provide access to different databases and to web resources. For example, there are packages for dealing with XML ([W3C](#)), and a SOAP client package ([Mein et al., 2002](#)), SSOAP, both available from the Omegahat project.

Visualization Capability

R has built-in support for many simple plots and graphs, including pie charts, bar charts, histograms, line graphs, and scatterplots. In addition, there are many graphical tools more specifically designed for bioinformatics analysis, such as the heatmap function, which is used to plot the expression levels of genes. Generally, R provides interactive plots so that users can query and navigate through them, and our future plans involve more such development.

Documentation

Most R packages provide an optional supplemental documentation, known as a vignette ([Gentleman et al., 2004](#)). Vignettes are provided in addition to the required documentation for R functions and datasets. Vignettes are written in order to share knowledge, and assist new users in learning the purpose and use of a package. A vignette is a document that integrates code and text, and describes how to perform a specific task. Vignettes were developed as part of the Bioconductor Project. They have since been incorporated as part of the R system. For developers, the Sweave system ([Leisch, 2002](#)) is well suited to creating and processing vignettes, and is the most widely used tool for programming in R.

Support for Parallel Computing

R supports parallel computing. In general, parallel computing refers to simultaneous calculations across multiple cores of multi-processor computer. Theoretically, procedures are trivial to parallelize. However, the development of a parallelized implementation that it also is robust and reliable is far from trivial. R provides an easy and powerful programming interface for the computational clusters. The interface allows the rapid development of R functions that allocate the calculations across the computational cluster. The approach can be extended to complex parallelization. There are different packages such as Rmpi ([Yu, 2009](#)), rpvm ([Li and Rossini, 2001](#)), snow ([Tierney et al., 2009](#)), and nws ([Schmidberger et al., 2009](#)) that support parallel computing. These tools provide simple interfaces that allow parallel computation of functions in concurrent R sessions. For example, the snow package provides a higher level of abstraction, independent of inter-processor communication technology (for instance, the message-passing interface (MPI) ([MPI Forum](#)), or the parallel virtual machine (PVM). A parallel random number generation ([Mascagni et al., 1999](#)), essential when distributing parts of stochastic simulations across a cluster, is provided by rsprng. More details about the benefits and problems involved with programming parallel processes in R are described in [Rossini et al. \(2007\)](#).

Illustrative Example of R Use

In this section, the practical use of R is presented, starting from R installation, and introducing basic concepts such as the creation of vectors, matrices, lists, dataframes, arrays, as well as functions.

R Installation

To use R, the user needs to install the R program his/her computer. R software is available from the Comprehensive R Network (CRAN) website, see Relevant Website section, a server on which both R releases, and a whole range of tools and additional implementations developed by the various developers, are available. The R download is available for Linux, Windows, and (Mac) OS X. After installation, the user starts to use R-GUI.

R Syntax

R is similar to other programming languages, such as C, Perl, or Python, and provides similar sets of mathematical operators (+, -, *, /, ^ (exponentiation), %% (modulo)), and logical operators (<, <=, >, >+, ==, !=, | (OR), & (AND), and isTRUE). Familiar loop control statements such as repeat, while, and for are available in R. R supports a flexible set of data types: logical, numeric, integer, complex, character, and raw byte. In programming, the user uses variables to store different information of various data types. In R, the variables are stored as R-Objects, and there are several basic types: Vectors, Matrices, Arrays, Lists, Factors, and Data Frames.

Vector

Vectors are a fundamental data type in R, and are composed of logical, integer, double, complex, character, or raw byte values. Implicitly, single values in R are vectors of length 1. To create a vector, the user should use the `c()` function, which combines the

listed elements into a vector. Vectors with an ordered set of elements can also be created using the `seq()` function. The basic syntax for creating a vector in R is:

```
c(data) or seq(begin, end, step)
```

where *data* indicates the elements of the vector. For `seq()`, *begin* and *end*, indicate the first and last element (inclusive), and *step* specifies the spacing between the values. Examples of creating vectors are shown below:

```
# Create vector using c()
v <- c('red','white','yellow')
print(v)
[1] "red" "white" "yellow"
# Create vector using seq()
v <- seq(5, 7, 0.5)
print(v)
[1] 5.0 5.5 6.0 6.5 7.0
```

Matrix

A matrix in R is a two-dimensional array, usually of numerical values, but characters or logical values can also be used. To create a matrix, the user should use the `matrix()` function. The basic syntax for creating a matrix in R is:

```
matrix(data, nrow, ncol)
```

where *data* is the input vector, which becomes the data elements of the matrix, *nrow* is the number of rows to be created, and *ncol* is the number of columns to be created. An example of creating a 2 by 3 matrix is shown below:

```
# Create matrix
m = matrix(c('1','2','3','4','5','6'), nrow = 2, ncol = 3)
print(m)
[, 1] [, 2] [, 3]
[1,] 1 2 3
[2,] 4 5 6
```

Array

Arrays store data in two or more dimensions. In R, arrays can store only one datatype. To create an array, the user should use the `array()` function. The basic syntax for creating an array in R is:

```
array(data, dim)
```

where *data* are the input vectors, and *dim* specifies the dimensions of the array.

An example of creating an array is shown below:

```
# Create two vectors
v1 <- c(1,2,3)
v2 <- c(4,5,6,7,8,9)

# Combine the vectors to create an array
z <- array(c(v1,v2), dim=c(3,3,2))
print(z)
„1
[, 1] [, 2] [, 3]
[1,] 1 4 7
[2,] 2 5 8
[3,] 3 6 9
„2
[, 1] [, 2] [, 3]
[1,] 1 4 7
[2,] 2 5 8
[3,] 3 6 9
```

List

Lists may contain data of different types. To create a list, the user should use **list()** function.

The basic syntax for creating an array in R is:

```
list(data)
```

where *data* may be strings, numbers, vectors and a logical values. An example to create a list is reported below:

```
# Create a list containing a mixture of string, vector, logical, and numerical values
# Note that the vector is stored in the list as a two element vector
list_example <- list("Flower", c(1,2), TRUE, 0.23)
print(list_example)
[[1]]
[1] "Flower"

[[2]]
[1] 1 2

[[3]]
[1] TRUE

[[4]]
[1] 0.23
```

Factor

A factor is used to store a set of data as a series of levels or categories. Factors can store either character or integer values. They are useful for data that has an enumerable number of discrete values such as male/female or north/south/east/west. To create a factor, the user should use the **factor()** function. The basic syntax for creating a factor in R is:

```
factor(data)
```

An example of creating a factor is shown below:

```
# Create a vector as input
data <- c("East", "West", "East", "North", "North", "East", "West", "West", "West", "East", "North")

# Apply the factor function
factor_data <- factor(data)
print(factor_data)
[1] East West East North North East West West West East North
Levels: East North West
```

Data frame

A data frame is a table in which each column contains values of one kind, and the rows correspond to a set of values. Data frames are typically used for experimental data, where the columns represent information or measured values, and the rows represent different samples. To create a data frame, the user should use **data.frame()** function.

The basic syntax for creating an array in R is:

```
data.frame(data)
```

where *data* are a collection of variables, which share many of the properties of matrices and of lists. An example of creating a data frame is shown below:

```
# Create three vectors
sample <- c(1, 2, 3)
v2 <- c('a', 'b', 'c')
v3 <- c(TRUE, TRUE, FALSE)

# Create a dataframe from the three vectors
df <- data.frame(sample, v2, v3)
print(df)
sample v2 v3
1      1 a TRUE
2      2 b TRUE
3      3 c FALSE
```

R Functions

Functions are subprograms that perform a narrowly defined task. A function consists of a set of statements; the function receives information from the main program, its arguments, and sends information back to the main program after it finishes, its return value. To create a R function, the user should use the keyword **function**. The basic syntax for defining a R function is:

```
FunctionName <- function (arg1, arg2, ...argn) {
  statements
  return(object)
}
```

where *FunctionName* is the name of function, stored in R as object, *arg1* to *argn* are the arguments of the function (i.e., the values the function will use in its calculation), *statements* are the tasks to perform, and *object* is the value of the function which is returned to the main program.

In addition to the functions in-built in R, the user can build personalized functions.

An example of creating a function is shown below:

```
# Create a function that computes the area of a triangle
triangle_area <- function(height, base){
  area <- (height*base) / 2
  return(area)
}
```

R Packages

Packages are collections of functions, compiled code from other languages, and sample data. Packages are stored in the R environment library, and many packages are automatically downloaded and installed during R installation. As mentioned above, additional user contributed packages are often downloaded during the course of an R analysis. The R package system is one of the strengths of R because it makes hundreds of advanced statistical and computational analyses available. Part of the beauty of the system is that any user can create and contribute their own packages. While creating a package involves some extra effort to create the required documentation, it is not particularly different. Complete instructions can be found in [Leisch \(2009\)](#).

Case Studies

In this section, an example of bioinformatics issues managed with R is described.

Biological Annotation

Many bioinformatic analyses rely on the processing of sequences and their metadata ([Leipzig, 2016](#)). Metadata is data that summarizes information about other data. There are two major challenges related to metadata ([Duval et al., 2002](#)). First, is the evolutionary nature of the metadata. In fact, as biological knowledge increases, metadata also changes and evolves. The second major problem that concerns metadata data is its complexity. In R, these issues are tackled by placing the metadata into R packages. These packages are constructed by a semi-automatic process ([Zhang et al., 2003](#)), and are distributed and updated using the package distribution tools in the *reposTools* package ([Core, 2002](#)). R contains many different types of annotation packages. There are packages that contain Gene Ontology (GO) ([Ashburner et al., 2000](#)), Kyoto Encyclopedia of Genes and Genomes (KEGG) ([Kanehisa and Goto, 2000](#)), and other annotations, and R can easily access NCBI, Biomart, UCSC, and other sources. For example, the *AnnotationDbi* ([Milano et al., 2014](#)) package provides increased flexibility, and makes linking various data sources simpler. The *AnnotationDbi* package ([Pages et al., 2008](#)) contains a collection of functions that can be used to make new microarray annotation packages. For example, the building of a chip annotation package consists of two-steps. The first step regards the construction of a database that conforms to a standard schema for the metadata of the organism that the chip is designed for. The use of a standard schema allows the new package to integrate with other annotation packages, such as *GO.db* and *KEGG.db*. The construction of a chip-specific database requires two inputs, a file containing the mapping between the chip identifiers, and a special intermediate database. This database contains information for all genes in the model organism, and many different biological IDs for data sources, such as Entrez Gene, KEGG, GO, and Uniprot. In the second step, the chip-specific database is applied to build an R package. The typical metadata used in Bioinformatics are the annotations, which provide useful and relevant in different applications that analyze biological data, e.g., in functional enrichment analyses, the use of GO to describe biological functions and processes, or in model bioinformatics applications, to guide the composition of workflows ([Milano et al., 2016](#)). Furthermore, annotations allow the comparison of molecules on the basis of semantics aspects through semantic similarity measures (SSMs) ([Milano et al., 2014](#)). In R there are different packages that compute of many SS measures, such as, *GOSemSim* ([Yu, 2010](#)), *GOVis* ([Heydebreck et al., 2004](#)), *csbl.go* ([Ovaska, 2016](#)). Among these tools *csbl.go* is the most widely used R Package for semantic analysis. It contains a set of functions for the calculation of semantic similarity measures, as

well as for clustering SS scores. It requires as input a list of GO Terms, or (in the case of proteins) a list of proteins, as well as the related annotations for each protein. It currently runs only for a subset of proteomes, but it may be extended by the user for the evaluation of semantic similarities to other proteomes. An example of an ad hoc function for the computation of semantic similarity using `csbl.go` is shown below:

```
SSM <- function(inputfile, tax, ontology, measure) {
  set.prob.table(organism=tax, type="similarity")
  ent <- entities.from.text(inputfile)
  SSM_result = entity.sim.many(ent,ontology,measure)
  return(SSM_result)
}
```

where *inputfile* is the set of Gene Ontology annotations, *tax* is the taxonomy (e.g., *Homo sapiens*; *Saccharomyces cerevisiae*; *Caenorhabditis elegans*; *Drosophila melanogaster*; *Mus musculus*; *Rattus norvegicus*), *ontology* indicates the GO ontology on which the semantic similarity is computed, the *measure* argument is one the following semantic similarity measures implemented in `csbl.go`: Resnik, Lin, JiangConrath, Relevance, ResnikGraSM, LinGraSM, JiangConrathGraSM, Kappa, Cosine, WeightedJaccard, or CzekanowskiDice.

Biographical Sketch

Marianna Milano received the Laurea degree in biomedical engineering from the University Magna Græcia of Catanzaro, Italy, in 2011. She is a PhD student at the University Magna Græcia of Catanzaro. Her main research interests are on biological data analysis and semantic-based analysis of biological data. She is a member of IEEE Computer Society.

Computing Languages for Bioinformatics: Java

Pietro H Guzzi, University “Magna Graecia” of Catanzaro, Catanzaro, Italy

© 2019 Elsevier Inc. All rights reserved.

Introduction

Java Programming language was designed by James Gosling, Mike Sheridan, and Patrick Naughton in early 1991. The syntax of Java is quite similar to C/C++ (Ellis and Stroustrup, 1990), therefore is based on the use of curly brackets to define code blocks and on the use of semicolons for each statement. The first public implementation of Java was released in 1995 by Sun Microsystems. Java was based on the use of a free Java Virtual Machine (JVM) available for almost all operating systems, able to execute the code, following the paradigm “Write Once, Run Anywhere” (WORA) (Arnold *et al.*, 2005).

Since first version, Java was designed with particular attention to security and network secure access to run java code (namely java applets) on web-browsers. The second version of Java (named Java 2 or J2SE), was more structured concerning Java 1 and more version of java were available. For instance, J2EE was designed for enterprise application while J2ME for mobile applications. JVM was initially released under GNU General Public License and on 2007 JVM code was available under free software/open-source distribution terms. Currently, Oracle detains the right of the Java.

The Structure of a Program in Java

As introduced before, the syntax of Java has been largely derived from C++ but it was built an object-oriented language. Consequently, all the data structures are represented as java objects (Bruegge and Dutoit, 2004).

All code is written inside classes, and every data item is an object except for primitive data types (i.e., integers, floating-point numbers, boolean values, and characters). Other differences with respect C++ are the absence of pointers and the lack of support for operator overloading and multiple inheritance for classes (Horstmann and Cornell, 2002). Java admits the definition of interfaces, i.e a reference type in Java that include a set of abstract methods. Classes implements the interfaces, i.e. they realise the abstract method, and a class may implement multiple interfaces, therefore realising a sort of multiple inheritance. Consequently, even a simple hello world application need the declaration of a class as follows.

```
public class helloworld {  
    public static void main (String args[]) {  
        System.out.println ("Hello World");  
    }  
}
```

The application code must be saved into a source files (with .java extension) that has the same name of the class containing the main method. Therefore the file containing the previous code must be named helloworld.java. It must first be compiled into bytecode, using a Java compiler, producing a file named HelloWorldApp.class. Only then can it be executed on a Java Virtual Machine.

It should be noted that three keywords are used for the main method: public, static and void. The keyword public it used for all the methods that may be called in other classes. This keyword is called access level modifier, other access level are private (a method that may be called only inside the same class) and protected (a method that is called inside classes from the same package). The keyword static indicates a method that is associated with the class and not with a specific object. Static methods cannot access any class members that are not also static. Methods that are not designated static are instance methods and require a specific instance of class to operate. The keyword void indicates that the main method does not return any value to the caller. The method name “main” is the name of the method the Java launcher calls to pass control to the program. The main method must accept an array of String objects.

Data Types in Java

Java is a statically-typed programming language, therefore each variable must be declared before the use by stating the type and the name of the variable. Java offers to the user eight primitive data types:

- Byte: The byte data type is an 8-bit signed two’s complement integer. It has a minimum value of -128 and a maximum value of 127 (inclusive).
- Short: The short data type is a 16-bit signed two’s complement integer. It has a minimum value of $-32,768$ and a maximum value of $32,767$ (inclusive).
- Int: The int data type is a 32-bit signed two’s complement integer, which has a minimum value of $-2,147,483,648$ and a maximum value of $2,147,483,647$.

- Long: The long data type is a 64-bit two's complement integer. The signed long has a minimum value of -2^{63} and a maximum value of $2^{63}-1$. (In Java 8 the programmer may also define a unsigned int and long).
- Float: The float data type is a single-precision 32-bit IEEE 754 floating point.
- Double: The double data type is a double-precision 64-bit IEEE 754 floating point.
- Boolean.
- Char: The char data type is a single 16-bit Unicode character.

Strings are represented by using the java.lang. String Class.

Data Structures in Java

Java does not define a set of primitive data structure, e.g. like Python, but many structure are available through the Java Collection Framework (JCF), a set of classes and interfaces that implement commonly reusable collection data structures. The JCF provides both interfaces that define various collections and classes that implement them.

Collections are derived from the java.util. Collection interface that defines the basic parts of all collections, including basic add(), remove() and contains() methods for adding to and removing from and to checks if a specified element is in the collection. All collections have an iterator that goes through all of the elements in the collection. From Java 1.6 any collection can be written to store any class. For example, Collection String can hold strings, and the elements from the collection can be used as strings.

Collections are subdivided into three main generic types: ordered lists, dictionaries/maps, and sets.

Two interfaces are included in the Ordered Lists which are the List Interface and the Queue Interface. Dictionaries/Maps store references to objects with a lookup key to access the object's values. One example of a key is an identification card. The Map Interface is included in the Dictionaries/Maps. Sets are unordered collections that can be iterated and where similar objects are not allowed. The Interface Set is included.

Creation and Running of a Program

Let suppose that a programmer wants to create a simple hello world application. He/she has to create a file (with .java extension) containing the main class with the same name of the class (helloworld.java in this case).

```
public class helloworld {
    public static void main (String args[] ) {
        System.out.println ("Hello World");
    }
}
```

It must first be compiled into bytecode, using a Java compiler, producing a file named helloworld.class, using the java compiler (javac helloworld.java). Finally, the program can be executed on a Java Virtual Machine, java helloworld.

Web Programming in Java

The possibility to run a code inside a web browser was one of the aims of the initial development of Java. Therefore a lot of effort has been made to ensure this possibility leading to the development of many Java-based technologies and programming models for the web. Among the others, we here report applets, servlets and Java Server Pages (JSP).

Java applets are programs that are embedded in other applications, typically in a Web page displayed in a web browser. Java Servlet technology provides a way to extend the functionality of a web server enabling the possibility to generate responses (typically HTML pages) to requests (typically HTTP requests) from clients. JavaServer Pages (JSP) are server-side Java EE components that generate responses, typically HTML pages, to HTTP requests from clients. JSP contains embedded java code in web pages. Each JSP page is compiled into a Java servlet the first time it is accessed. Then it is executed securely.

Concurrency in Java

The Java programming language and the Java virtual machine (JVM) have been designed to support concurrent programming. The programming model is based on threads: each thread has its path of execution. The programmer must take care of the safely read and write access to objects, accessible by many threads, in a synchronized way. Synchronization ensures that objects are modified by only one thread at a time. The Java language has built-in constructs to support this coordination.

Threads are also called lightweight processes, and a program in Java usually runs as a single process. Each thread is associated with an instance of the class Thread. Every application has at least one thread (defined as main thread) that may create additional

threads called Runnable objects (or Callable in recent versions). All the threads share the process's resources, including memory and open files. The mapping among java threads and OS threads is different on each operating systems and JVM implementation.

There are different ways two start a thread; we here present the use of class Thread and the use of the interface Runnable.

```
// using the interface Runnable

public class HelloRunnable implements Runnable {
    @Override
    public void run(){
        System.out.println("Hello from thread!");
    }
    public static void main(String[] args) {
        (new Thread(new HelloRunnable())).start();
    }
}

// Extension of the class Thread

public class HelloThread extends Thread {
    @Override
    public void run() {
        System.out.println("Hello from thread!");
    }
    public static void main(String[] args) {
        (new HelloThread()).start();
    }
}
```

Java for Bioinformatics: BioJava

BioJava ([Prlić *et al.*, 2012](#)) is an open-source software project offering libraries and tools to manage biological data such as sequences, protein structures, file parsers, Distributed Annotation System (DAS), and simple statistical algorithms. Using BioJava researches may transparently manage DNA and protein sequences as well as protein structures. BioJava is based on an application programming interface (API) supporting file parsers, database access, data models and algorithms.

Parallel Architectures for Bioinformatics

Ivan Merelli, Institute for Biomedical Technologies (CNR), Milan, Italy and National Research Council, Segrate, Italy

© 2019 Elsevier Inc. All rights reserved.

Introduction

The increasing availability of omic data resulting from improvements in molecular biology experimental techniques represents an unprecedented opportunity for Bioinformatics and Computational Biology, but also a major challenge (Fuller *et al.*, 2013). Due to the increased number of experiments involving genomic research, in particular due to the spreading of these techniques in hospitals, the amount and complexity of biological data is increasing very fast.

In particular, the high demand for low-cost sequencing has driven the development of high-throughput technologies that parallelize the sequencing process, producing millions of sequences concurrently (Church, 2006). High-throughput, or next-generation, sequencing (NGS) applies to genome sequencing, genome resequencing, transcriptome profiling (RNA-Seq), DNA-protein interactions (ChIP-sequencing), and epigenome characterization (de Magalhães *et al.*, 2010).

Such huge and heterogeneous amount of digital information is an incredible resource for uncovering disease associated hidden patterns in data (Merelli *et al.*, 2013), allowing the creation of predictive models for real-life biomedical applications (Alfieri *et al.*, 2008). But suitable analysis tools should be available to life scientists, biologists and physicians to properly treat this information in a fast and reliable way.

Due to the huge volume of information daily produced, it is almost impossible to process all data using an ordinary desktop machine in standalone executions. Since most of the analysis have non-linear complexity, the need for computational power to perform bioinformatic analysis grows very fast. Scientists need to use high-performance computing (HPC) environments together with parallel techniques to process all the produced data in a reasonable time.

Several large-scale bioinformatic projects already benefit from parallelization techniques and HPC infrastructures (Pérez-Sánchez *et al.*, 2015), in particular considering clusters of high-end servers connected by fast networks. Indeed, most of the modern supercomputers run, among the others, applications from the computational biology domain, since Bioinformatics provides impressive developing and testing opportunities for research in HPC applications. Some vast, rich, and complex bioinformatic areas related to genomics can also benefit from HPC infrastructures and parallel techniques, such as NGS, Proteomics, Transcriptomics, Metagenomics, and Structural Bioinformatics.

More recently, the development of cards harbouring hundreds of cores changed the paradigm of parallel computing, generating a large impact also in High Performance Bioinformatics. Starting from 2010, graphics processing units (GPUs), specialized computer processors addressing real-time compute-intensive 3D graphic tasks, evolved into highly parallel multi-core systems allowing very efficient manipulation of large blocks of data. These architectures are more effective than general-purpose central processing unit (CPUs) for algorithms that require processing large blocks of data in parallel. The drawback is that algorithms should be reimplemented to exploit the vectorized architecture of these devices and much work is necessary to optimize their performance.

Although many devices are available for GPU computing, the most popular cards are manufactured by NVIDIA, which also developed a parallel computing platform and application programming interface (API) called Compute Unified Device Architecture (CUDA) (Nickolls *et al.*, 2008). This framework allows software developers and software engineers to use CUDA-enabled GPUs, providing a software layer that gives direct access to the GPU parallel computational elements, for the execution of compute kernels. CUDA has been largely used in Bioinformatics, in particular in the field of structural biology, although not all the applications are suitable for this kind of implementation.

On the other hand, x86 compatible coprocessors have been developed to exploit hundreds of cores without the need of reimplementing any algorithm. The most popular of these cards is the Intel XeonPhi. Thanks to their x86 architecture, XeonPhi allows the use of standard programming language APIs, such as OpenMP (Dagum and Menon, 1998). Although these cards have a nominal performance that exceed 1 Tflops, their naive usage for bioinformatic applications is usually unsuccessful. As for GPU cards, the real challenge is the optimization of the code to exploit the architecture at the best of its capability, which has been achieved for few applications, in particular of molecular dynamics.

Parallelization Paradigms

Classification of parallel programming models can be divided broadly into two areas: process interaction and problem decomposition (Foster, 1995). Process interaction relates to the mechanisms by which parallel processes are able to communicate with each other. The most common forms of interaction are shared memory and message passing, although other approaches are possible (McBurney and Sleep, 1987).

Shared memory is an efficient means of passing data between processes. In a shared-memory model, parallel processes share a global address space that they read and write asynchronously. Asynchronous concurrent accesses can lead to race conditions and mechanisms such as locks, semaphores and monitors can be used to avoid these. Conventional multi-core processors directly

support shared memory, which many parallel programming languages and libraries, such as OpenMP (Dagum and Menon, 1998) and Threading Building Blocks (TBB) (Pheatt, 2008), are designed to exploit. This approach is typically used in Bioinformatics to parallelize applications within a single server or device.

In the message-passing model, parallel processes exchange data through passing messages to one another. These communications can be asynchronous, where a message can be sent before the receiver is ready, or synchronous, where the receiver must be ready. The Communicating Sequential Processes (CSP) formalisation of message passing uses synchronous communication channels to connect processes, leading to important languages such as Occam, Limbo and Go. In contrast, the actor model uses asynchronous message passing and has been employed in the design of languages such as Scala (Odersky *et al.*, 2004). However, the most popular approach for developing software using the message-passing model are language specific libraries that implement the Message Passing Interface standard, which defines the syntax and semantics of routines useful to write portable parallel programs (Gropp *et al.*, 1999).

Problem decomposition relates to the way in which the simultaneously executing processes of a parallel program are formulated (Foster, 1995). A task-parallel model focuses on processes, or threads of execution. These processes will often be behaviourally distinct, which emphasises the need for communication. Task parallelism is a natural way to express message-passing communication. On the other hand, a data-parallel model focuses on performing operations on a data set, typically a regularly structured array. A set of tasks will operate on this data, but independently on disjoint partitions. Data parallel applications are very common in Bioinformatics, in particular for sequence analysis.

Parallel Computing Platforms

The traditional platforms for operating parallel bioinformatic analysis are computer clusters (Merelli *et al.*, 2014), although parallel on-chip acceleration devices are commonly used to speed up the computation on desktop computers. In this section we will briefly review bioinformatic applications or projects exploiting these platforms.

Cluster Computing

The key issues while developing applications using data parallelism are the choice of the algorithm, the strategy for data decomposition, load balancing among possibly heterogeneous computing nodes, and the overall accuracy of the results (Rencuzogullari and Dwardadas, 2001).

The data parallel approach, that is the parallelization paradigm by which data are analysed by almost independent processes, is a suitable solution for many kinds of bioinformatic analysis. Indeed, the computation on biological data can be usually split in independent tasks, collecting and re-ranking results at the end. The possibility of working on each sequence independently makes data parallel approaches resulting in high scalability and performance figures for many bioinformatic applications.

This approach is generally compatible with clusters of computers, which can be combined to support the computational load. However, if processes need a lot of communication to accomplish their tasks, for example, due to complex post-processing analysis, it is important to have fast interconnecting networks, otherwise the scalability can be largely impaired. Importantly, the key feature to achieve good performance is to have low-latency networks (Fibre Channel, InfiniBand, Omni-Path, etc.), more than high-throughput networks (i.e., 10 Gigabit Ethernet).

An example of analysis that heavily relies on computer clusters and low-latency interconnecting networks is the *de novo* assembly of genomes. These approaches typically work finding the fragments that *overlap* in the sequencing reads and recording these overlaps in a huge diagram called de Bruijn (or assembly) graph (Compeau *et al.*, 2011). For a large genome, this graph can occupy many Terabytes of RAM, and completing the genome sequence can require days of computation on a world-class supercomputer. This is the reason why memory distributed approaches, such as Abyss (Simpson *et al.*, 2009), are now widely exploited, although algorithms that efficiently use multiple servers are difficult to implement and they are still under active development.

Virtual Clusters

Clusters can be also build in a virtualized manner on cloud, by using the on-demand paradigm. There are many tools for the automatic instantiation of clusters on virtual resources, which help users to manage node images, network connections and storage facilities. An example of such software is *AlcesFlight* (2016), which provides scalable High Performance Computing (HPC) environments, complete with job scheduler and applications, for research and scientific computing relying both on-demand and spot instances.

Concerning performance, virtual clusters should be also considered as very reliable in this cloud era: for example, a virtual infrastructure of 17,024 cores built using a set of Amazon Elastic Cloud Computing virtual machines was able to achieve 240.09 TeraFLOPS for the High Performance Linpack benchmark, placing the cluster at position 102 in the November 2011 Top500 list. A similar example was performed on Windows Azure, bringing together 8064 cores for a total of 151.3 TeraFLOPS, a virtual cluster that reached position 165 in the November 2011 Top500 list.

Virtual clusters are commonly used in Bioinformatics, for example, in the frame of drug discovery projects (D'Agostino *et al.*, 2013), which requires the screening of large datasets of ligands against a target protein (Chiappori *et al.*, 2013). Considering that each docking software is typically optimized for specific target families, it is usually a good idea to test many of them (Morris *et al.*, 2009; Mukherjee *et al.*, 2010; Friesner *et al.*, 2006; Merelli *et al.*, 2011), which increases the need for computational power. Moreover, side effects caused by off-target bindings should be avoided, therefore the most promising compounds are usually tested against many other proteins, which also requires time-consuming screenings.

GPU Computing

Driven by the demand of the game industry, GPUs have completed a steady transition from mainframes to workstations PC cards, where they emerge nowadays like a solid and compelling alternative to traditional parallel computing platforms. GPUs deliver extremely high floating-point performance and massively parallelism at a very low cost, thus promoting a new concept of the high performance computing market. For example, in heterogeneous computing, processors with different characteristics work together to enhance the application performance taking care of the power budget. This fact has attracted many researchers and encouraged the use of GPUs in a broader range of applications, particularly in the field of Bioinformatics. Developers are required to leverage this new landscape of computation with new programming models, which make easier the developers' task of writing programs to run efficiently on such platforms altogether (Garland *et al.*, 2008).

The most popular graphic card producers, such as NVIDIA and ATI/AMD, have developed hardware products aimed specifically at the heterogeneous or massively parallel computing market. The most popular devices are Tesla cards, produced by NVIDIA, and Fire-stream cards, which is the AMDs device line. They have also released software components, which provide simpler access to this computing power. Compute Unified Device Architecture (CUDA) is the NVIDIA solution for a simple block-based programming, while the AMDs alternative was called Stream Computing.

Although these efforts in developing programming models have made great contributions to leverage the capabilities of these platforms, developers have to deal with a massively parallel on-chip architectures (Garland and Kirk, 2010), which is quite different than working on traditional computing architectures. Therefore, programmability on these platforms is still a challenge, in particular concerning the fine-tuning of applications to get high scalability. Many research efforts have provided abstraction layers avoiding dealing with the hardware particularities of these accelerators and also extracting transparently high level of performance, providing portability across operating systems, host CPUs, and accelerators.

For example, OpenCL (Khronos Group, 2014) emerged as an attempt to unify all these models with a superset of features, being the best broadly supported multi-platform data parallel programming interface for heterogeneous computing, including GPUs, accelerators, and similar devices. However, other libraries and interfaces exist for developing with popular programming languages, like OpenMP or OpenACC, which describe a collection of compiler directives to specify loops and regions of code to parallelize in standard programming languages such as C, C++, or Fortran. Although the complexity of these architectures is high, the performance that such devices are able to provide justifies the great interest and efforts in porting bioinformatic applications on them (NVIDIA, 2016).

In Bioinformatics, one of the most successful application of GPUs concerns Molecular Dynamics simulations (Chiappori *et al.*, 2012). Molecular Dynamics is certainly the most CPU-demanding application in Computational Biology, because it consists in solving time step after time step the Newton's equations of motion for all the atoms of a bio-molecular system, taking as boundary conditions the initial macromolecular structure and a set of velocity taken from a Gaussian distribution.

Molecular Dynamics is often employed in combination with docking screenings, because while virtual screening is very useful for discarding compounds that clearly do not fit with the protein target, the identification of lead compounds is usually more challenging (Chiappori *et al.*, 2016). The reason is that docking software have biases in computing binding energy in the range of few kcal (Chiappori *et al.*, 2016). Therefore, best compounds achieved through the virtual screening process usually undergone to a protocol of energy refinement implemented using Molecular Dynamics (Alonso *et al.*, 2006).

Indeed, by employing specific simulation schemas and energy decomposition algorithms in the post-analysis, Molecular Dynamics allows to achieve more precise quantification of the binding energy (Huey *et al.*, 2007). Common techniques for energy estimation are MM-PBSA and MM-GBSA, which consist in the evaluation of the different terms that compose the binding energy taking into account different time points. For example, it is possible to estimate the binding energy as the sum of the molecular mechanical energies in the gas phase, the solvation contribute, evaluated using an implicit solvent model like the Generalized Born or solving the Poisson-Boltzman equations, and the entropic contribute, estimated with normal mode analysis approximation.

Moreover, Molecular Dynamics can be used to predict protein structures, ab-initio or refining models computed by homology, or to analyse protein stability, for example, verifying what happens in case of mutations. The simulation of proteins can be also very useful to verify the interactions of residues within a macromolecule, for example, to clarify why the binding of certain nucleotides (such as ATP) can change the structure of a particular binding site, a phenomenon that is usually referred as allostery.

The possibility of using NVIDIA cards for Molecular Dynamics in computational chemistry and biology propelled researches to new boundaries of discovery, enabling its application in wider range of situations. Compared to CPUs, GPUs run common molecular dynamics, quantum chemistry and visualization applications more than $5 \times$ faster. In particular, the team of AMBER has worked very hard to improve the performance of their simulator on GPUs, which is now extremely fast, between $5 \times$ and $10 \times$, depending on the number of atoms, the composition of the system and the type of simulation desired.

(Amber on GPUs, 2014). Also GROMACS7 has been ported on GPUs (GROMACS, 2012), with very good performance when the implicit solvent is used, while performance are less brilliant in case of explicit solvent.

XeonPhi Computing

Relying on Intel's Many Integrated Core (MIC) x86-based architecture, Intel Xeon Phi coprocessors provide up to 61 cores and 1.2 Teraflops of performance. These devices equip the second supercomputer of the TOP500 list (November 2016), Tianhe-2. In terms of usability, there are two ways an application can use an Intel Xeon Phi: in offload mode or in native mode. In offload mode the main application is running on the host, and it only offloads selected (highly parallel, computationally intensive) work to the coprocessor. In native mode the application runs independently, on the Xeon Phi only, and can communicate with the main processor or other coprocessors through the system bus.

The performance of these devices heavily depends on how well the application fits the parallelization paradigm of the Xeon Phi and in relation to the optimizations that are performed. In fact, since the processors on the Xeon Phi have a lower clock frequency with respect to the common Intel processor units (such as, e.g., the Sandy Bridge), applications that have long sequential algorithmic parts are absolutely not suitable for the native mode. On the other hand, even if the programming paradigm of these devices is standard C/C++ , which makes their use simpler with respect to the necessity of exploiting a different programming language such as CUDA, in order to achieve good performance, the code must be heavily optimized to fit the characteristics of the coprocessor (i.e., exploiting optimizations introduced by the Intel compiler and the MKL library).

Looking at the performance tests released by Intel (2015), the baseline improvement of supporting two Intel Sandy Bridge by offloading the heavy parallel computational to an Intel Xeon Phi gives an average improvement of 1.5 in the scalability of the application that can reach up to 4.5 of gain after a strong optimization of the code. For example, considering typical tools for bioinformatic sequence analysis: BWA (Burrows-Wheeler Alignment) (Li and Durbin, 2009) reached a baseline improvement of 1.86 and HMMER of 1.56 (Finn *et al.*, 2011). With a basic recompilation of Blastn for the Intel Xeon Phi (Altschul *et al.*, 1990) there is an improvement of 1.3, which reaches 4.5 after some modifications to the code in order to improve the parallelization approach. Same scalability figures for Abyss, which scales 1.24 with a basic porting and 4.2 with optimizations in the distribution of the computational load. Really good performance is achieved for Bowtie, which improves the code passing from a scalability of 1.3–18.4.

Clearly, the real competitors of the Intel Xeon Phi are the GPU devices. At the moment, the comparison between the best devices provided by Intel (Xeon Phi 7100) and Nvidia (Tesla K40) shows that the GPU is on average 30% more performing (Fang *et al.*, 2014), but the situation can vary in the future.

Low Power Devices

Over the recent years, energy efficiency has become a first order concern in the high performance computing sector. While high-end processors are rapidly shifting toward power-efficient technologies, the newer Systems-on-Chip (SoC), designed to meet the requirements of the mobile and embedded market, are gaining the interest of the scientific community for their increasing computing performances.

In addition, we should not underestimate the appealing low cost and low power consumption of SoCs. These novel hardware platforms are integrated circuits typically composed of low power multi-core processors combined with a small graphics-processing unit so, in principle, it is possible to run scientific applications on SoCs, with the aim of improving energy-to-performance ratios. However, such devices present a number of limitations for realistic scientific workloads, ranging from their 32-bit still present in some models to their small caches and RAM sizes.

There are examples of bioinformatic applications developed on SoCs architectures, although the diffusion of such cards is still limited and most of the available software is mainly demonstrative. For example, in the context of computational biology, a tool has been developed for the analysis of microRNA target (Morganti *et al.*, 2017), while in the context of systems biology a simulator has been developed to model reaction-diffusion systems (Beretta *et al.*, 2017).

Intriguingly, low-power architectures can be used to build portable bioinformatic applications for supporting portable sequencing machine such as the Oxford Nanopore Minion (Jain *et al.*, 2016). This will lead to the direct analysis of genomes of humans, animals or plants in remote regions of the world, or to analyse the composition of the microbioma in air-filters, water or soil samples in a simple and portable way.

Supercomputing

Many of the supercomputers in the TOP500 list are heavily involved in computational biology research. For example, Titan, one of the fastest system in the TOP500 list of November 2016, works for providing a molecular description of membrane fusion, one of the most common ways for molecules to enter or exit from living cells. Looking at the top supercomputers of this latest TOP500 list, the SuperMUC cluster, installed at the Leibniz Supercomputer Centre in Monaco, is often employed in Bioinformatics, for example, in analysis of linkage disequilibrium and genotyping, while Piz Daint, installed at the CSCS/Swiss Bioinformatics Institute in Lugano, has been successfully employed for a challenge of evolutionary genomics, for quickly calculating selection events in genes as consequence of mutations.

Looking at the November 2016 list, it is very interesting to see that two of the top three supercomputers in the world make use of co-processors to improve their performance. In particular, Tianhe-2 has more than 16,000 nodes, organized in unit of two Processor Intel Xeon E5 and three Coprocessor Intel Xeon Phi 31S1, while Titan uses NVIDIA K20 cards to improve its performance. Notably, in the top ten supercomputers, four make use of co-processors to enhance their performance. This choice should also be analysed in the view of the power consumption of these supercomputers: Tianhe-2 has a declared power consumption of 17 GW for a total of 33 PetaFLOPS, while Titan has a power consumption of 8 W for a total of 17 PetaFLOPS. For example, the K supercomputer, installed at the Riken Institute of Japan, has a power consumption of 12 GW for 10.5 PetaFLOPS. The possibility of saving energy using co-processors is therefore clear.

Conclusions

Omic sciences are able to produce, with the modern high-throughput techniques of analytical chemistry and molecular biology a huge amount of data. Next generation sequencing analysis of diseased somatic cells, novel bioactive compounds discovery and design, genome wide identification of regulatory elements and bio-markers, systems biology studies of biochemical pathways and gene networks are examples of the great advantages that high-performance computing can provide to omic sciences, accelerating a fast translation of bio-molecular results to the clinical practice.

Massive parallel clusters and supercomputers have huge capabilities, but their use by clinical and healthcare experts can be difficult. On the other hand, on-chip supercomputing such as GPU and Xeon Phi devices can represent good solutions to run custom bioinformatic algorithms, at least in institutions that perform routinely analysis. Virtual clusters on cloud can be a good trade-off between the necessity of computer power to run bioinformatic applications and the flexibility required to deal with heterogeneous data. Although this solution can be costly, a careful mix of on-demand resources and spot instances can be the key to face bioinformatic computational problems in the years to come.

Models and Languages for High-Performance Computing

Domenico Talia, University of Calabria, Rende, Italy

© 2019 Elsevier Inc. All rights reserved.

Introduction

Programming models, languages, and frameworks for parallel computers are required tools for designing and implementing high performance applications on scalable architectures. During recent years, parallel computers ranging from tens to hundred thousands processors became commercially available. They are gaining recognition as powerful instruments in scientific research, information management, and engineering applications. This trend is driven by parallel programming languages and tools that make parallel computers useful in supporting a wide range of applications, from scientific computing to business intelligence.

Parallel programming languages (called also *concurrent languages*) permit the design of parallel algorithms as a set of concurrent actions mapped onto different computing elements (Skillicorn and Talia, 1994). The cooperation between two or more actions can be performed in many ways according to the selected language. The design of programming languages and software tools for high-performance computing is crucial for the large dissemination and efficient utilization of these novel architectures (Skillicorn and Talia, 1998). High-level languages decrease both the design time and the execution time of parallel applications, and make it easier for new users to approach parallel computers.

Several issues must be solved when a parallel program is to be designed and implemented. Many of these are questions specifically related to the nature of parallel computation, such as process structuring, communication, synchronization, deadlock, process-to-processor mapping and distributed termination. For solving these questions in the design of an efficient parallel application it is important to use a programming methodology that helps a designer/programmer in all the stages of parallel software development. A parallel programming methodology must address the following main issues:

1. *Parallel process structuring*: how to decompose a problem in a set of parallel actions;
2. *Inter-process communication and synchronization*: how the parallel actions cooperate to solve a problem;
3. *Global computation design and evaluation*: how to see globally at the parallel program (as a whole) to improve its structure and evaluate its computational costs;
4. *Process-to-processor mapping*: how to assign the processes that compose a program to the processors that compose a parallel computer.

Parallel programming languages offer a user a support in all the phases of the parallel program development process. They provide constructs, mechanisms, and techniques that support a methodology for parallel software design that addresses the problems listed above. Although, early parallel languages and more recent low-level tools do not provide good solutions for all the mentioned problems, in the recent years significant high-level languages and environments have been developed. They can be used in all or many phases of the parallel software development process to improve scalability and portability of applications.

We discuss here representative languages and tools designed to support different models of parallelism and analyze both languages currently used to develop parallel applications in many areas, from numerical to symbolic computing, and novel parallel programming languages that will be used to program parallel computers in a near future.

Shared Memory Languages

Parallel languages of this class use the shared-memory model that is implemented by parallel machines composed by several processors that share the main memory. The concept of shared memory is a useful way to separate program control flow issues from data mapping, communication, and synchronization issues. Physical shared memory is probably difficult to provide on massively parallel architectures, but it is a useful abstraction, even if the implementation it hides is distributed. Significant parallel languages and environments based on the shared-memory model are OpenCL, Linda, OpenMP, Java, Pthreads, Opus, SHMEM, ThreadMarks, and Ease.

One way to make programming easier is to use techniques adapted from operating systems to enclose accesses to shared data in critical sections. Thus a single access to each shared variable is guaranteed at a given time. Another approach is to provide a high-level abstraction of shared memory. One way to do this is called *virtual shared memory* or *distributed shared memory*. In this case, the programming languages present a view of memory as if it is shared, but the implementation may or may not be. The goal of such approaches is to emulate shared memory well enough that the same number of messages travel around the system when a program executes as would have travelled if the program had been written to pass messages explicitly. In other words, the emulation of shared memory imposes no extra message traffic. Examples of these models and systems are Linda, Threadmarks, SHMEM, and Munin.

These systems emulate shared memory on distributed memory hardware by extending techniques for cache coherence in multiprocessors to software memory coherence. This involves weakening the implementation semantics of coherence as much as possible to make the problem tractable, and then managing memory units at the operating system level. Munin is a system that

supports different consistency models in the implementation of distributed shared memory (Bennett et al., 1990). It implements a type-specific memory coherence scheme that uses different coherence models. Thus, in Munin, each shared data object is supported by a memory coherence mechanism appropriate to the way in which the object is accessed. The other way is to build a programming model based on a useful set of sharing primitives for implementing shared data accessed through user-defined operations. This is the approach used by the Orca language.

Here we describe the main features of two shared-memory parallel languages: OpenMP and Java.

OpenMP

OpenMP is a library (*application program interface* or *API*) that supports parallel programming on shared memory parallel computers (OpenMP Consortium, 2002). OpenMP has been developed by a consortium of vendors of parallel computers (DEC, HP, SGI, Sun, Intel, etc.) with the aim to have a standard programming interface for parallel *shared-memory machines* (like PVM and MPI for distributed memory machines).

The OpenMP functions can be used inside Fortran, C and C++ programs. They allow for the parallel execution of code (*parallel DO loop*), the definition of shared data (*SHARED*), and synchronization of processes. OpenMP allows a user to.

- define regions of parallel code (*PARALLEL*) where it is possible to use local (*PRIVATE*) and shared variables (*SHARED*);
- synchronize processes by the definition of critical sections (*CRITICAL*) for shared variables (*SHARED*);
- define synchronization points (*BARRIER*).

A standard OpenMP program begins its execution as a single task, but when a *PARALLEL* construct is encountered, a set of processes are spawned to execute the corresponding parallel region of code. Each process is assigned with an iteration. When the execution of a parallel region ends, the results are used to update the data of the original process, which then resume its execution. From this operational way, it could be deduced that support for general task parallelism is not included in the OpenMP specification. Moreover, constructs or directives for data distribution control are absent from the current releases of OpenMP. This parallel programming library solves portability of code across different shared-memory architectures, however it does not offer a high-level programming level for parallel software development.

Java

Java is a language that is popular because of its connection with platform-independent software delivery on the Web (Lea, 2000). However, it is an object-oriented language that embodies also a shared-memory parallel programming model. Java supports the implementation of concurrent programs by process (called *threads*) creation (*new*) and execution (*start*). For example, the following Java instructions create three processes:

```
new proc (arg1a, arg1b, ..) ;
new proc (arg2a, arg2b, ..) ;
new proc (arg3a, arg3b, ..) ;
```

where *proc* is an object of the *Thread* class.

Java *threads* communicate and synchronize through *condition* variables. Shared variables are accessed from within *synchronized* methods. Java programs execute *synchronized* methods in a mutually exclusive way generating a critical section by associating a lock with each object that has synchronized methods. *Wait* and *notify* constructs have been defined to handle locks. The *wait* operation allows a thread to relinquish its lock and wait for notification of a given event. The *notify* operation allows a thread to signal the occurrence of an event to another thread that is waiting for that specific event. However, the *notify* and *wait* operations must be explicitly invoked within critical sections, rather than being automatically associated with section entry and exit as occurs in the *monitor* construct proposed about two decades ago. Thus a programmer must be careful to avoid deadlock occurrence among Java threads; the language offers no support for deadlock detection.

The shared-memory programming model has been defined for using Java on a sequential computer (*pseudo-parallelism*) or on shared-memory parallel computers. However, although the concurrent model defined in Java is based on the shared-memory model, Java was mainly designed to implement software on the Internet. Therefore it must be able to support the implementation of distributed programs on computer networks. To use Java on such platforms or on distributed-memory parallel computers there are different approaches presented in section "Object-Oriented Parallel Languages".

Distributed Memory Languages

A parallel program in a distributed-memory parallel computer (*multicomputer*) is composed of several processes that cooperate by exchanging data, e.g. by using messages. The processes might be executed on different processing elements of the multicomputer. In this environment, a high-level distributed concurrent programming language offers an abstraction level in which resources are defined like abstract data types encapsulated into cooperating processes. This approach reflects the model of distributed memory architectures composed of a set of processors connected by a communication network.

This section discusses imperative languages for distributed programming. Other approaches are available such as logic, functional, and object-oriented languages. This last class is discussed in Section "Object-Oriented Parallel Languages". Parallelism

in imperative languages is generally expressed at the level of processes composed of a list of statements. We included here both languages based on control parallelism and languages based on data parallelism. Control parallel languages use different mechanisms for process creation (e.g., *fork/join*, *par*, *spawn*) and process cooperation and communication (e.g., *send/receive*, *rendez-vous*, *remote procedure call*). On the other hand, data parallel languages use an implicit approach in solving these issues. Thus their run-time systems implement process creation and cooperation transparently to users. For this reason, data parallel languages are easier to be used, although they do not allow programmers to define arbitrary computation forms as occurs with control parallel languages.

Distributed memory languages and tools are: Ada, CSP, Occam, Concurrent C, CILK, HPF, MPI, C*, and Map-Reduce. Some of these are complete languages while others are APIs, libraries or *toolkits* that are used inside sequential languages. We discuss here some of them, in particular we focus on the most used languages for scientific applications, such as MPI and HPF.

MPI

The *Message Passing Interface* or MPI (Snir et al., 1996) is a de-facto standard message-passing interface for parallel applications defined since 1992 by a forum with a participation of over 40 organizations. MPI-1 was the first version of this message passing library that has been extended in 1997 by MPI-2 and in 2012 by MPI-3. MPI-1 provides a *rich set* of messaging primitives (129), including point-to-point communication, broadcasting, barrier, reduce, and the ability to collect processes in groups and communicate only within each group. MPI has been implemented on massively parallel computers, workstation networks, PCs, etc., so MPI programs are portable on a very large set of parallel and sequential architectures.

An MPI parallel program is composed of a set of similar processes running on different processors that use MPI functions for message passing. A single MPI process can be executed on each processor of a parallel computer and, according the SPMD (Single Program Multiple Data) model, all the MPI processes that compose a parallel program execute the same code on different data. Examples of MPI point-to-point communication primitives are.

```
MPI_Send (msg, leng, type,..., tag, MPI_COM);
MPI_Recv (msg, leng, type,0, tag, MPI_COM, &st);
```

Group communication is implemented by the primitives:

```
MPI_Bcast (inbuf, incnt, intype, root, comm);
MPI_Gather (outbuf, outcnt, outtype, inbuf, incnt,...);
MPI_Reduce (inbuf, outbuf, count, typ, op, root,...);
```

For program initialization and termination the *MPI_init* and *MPI_Finalize* functions are used. MPI offers a low-level programming model, but it is widely used for its portability and its efficiency. It is the case to mention that MPI-1 does not make any provision for process creation. However, in the MPI-2 and MPI-3 versions additional features have been provided for the implementation of.

- active messages,
- process startup, and
- dynamic process creation.

MPI is becoming more and more the first programming tool for message-passing parallel computers. However, it should be used as an *Esperanto* for programming portable system-oriented software rather than for end-user parallel applications where higher level languages could simplify the programmer task in comparison with MPI.

HPF

Differently from the previous toolkits, *High Performance Fortran* or HPF is a complete parallel language (Loveman, 1993). HPF is the result of an industry/academia/user effort to define a de facto consensus on language extensions for Fortran-90 to improve data locality, especially for distributed-memory parallel computers. It is a language for programming computationally intensive scientific applications. A programmer writes the program in HPF using the Single Program Multiple Data (SPMD) style and provides information about desired data locality or distribution by annotating the code with *data-mapping directives*. Examples of data-mapping directives are *Align* and *Distribute*:

```
!HPF$ Distribute D2 (Block, Block).
!HPF$ Align A(I,J) with B(I+2, J+2).
```

An HPF program is compiled by an architecture-specific compiler. The compiler generates the appropriate code optimized for the selected architecture. According to this approach, HPF could be used also on shared-memory parallel computers. HPF is based on exploitation of *loop parallelism*. Iterations of the loop body that are conceptually independent can be executed concurrently. For example, in the following loop the operations on the different elements of the matrix A are executed in parallel.

```
ForAll (I = 1: N, J = 1: M).
  A(I,J) = I * B(J).
End ForAll.
```

HPF must be considered as a high level parallel language because the programmer does not need to explicitly specify parallelism and process-to-process communication. The HPF compiler must be able to identify code that can be executed in parallel and

it implements inter-process communication. So HPF offers a higher programming level with respect to PVM or MPI. On the other hand, HPF does not allow for the exploitation of control parallelism and in some cases (e.g., irregular computations) the compiler is not able to identify all the parallelism that can be exploited in a parallel program, and thus it does not generate efficient code for parallel architectures.

Object-Oriented Parallel Languages

The parallel object-oriented paradigm is obtained by combining the parallelism concepts of process activation and communication with the object-oriented concepts of modularity, data abstraction and inheritance (Yonezawa *et al.*, 1987). An object is a unit that encapsulates private data and a set of associated operations or *methods* that manipulate the data and define the object behavior. The list of operations associated with an object is called its *class*. Object-oriented languages are mainly intended for structuring programs in a simple and modular way reflecting the structure of the problem to be solved.

Sequential object-oriented languages are based on a concept of passive objects. At any time, during the program execution only one object is active. An object becomes active when it receives a request (message) from another object. While the receiver is active, the sender is passive waiting for the result. After returning the result, the receiver becomes passive again and the sender continues. Examples of sequential object-oriented languages are Simula, Smalltalk, C++ , and Eiffel.

Objects and parallelism can be nicely integrated since object modularity makes them a natural unit for parallel execution. Parallelism in object-oriented languages can be exploited in two principal ways:

- using objects as the unit of parallelism assigning one or more processes to each object;
- defining processes as components of the language.

In the first approach languages are based on active objects. Each process is bound to a particular object for which it is created. When one process is assigned to an object, *inter-object* parallelism is exploited. If multiple processes execute concurrently within an object, *intra-object* parallelism is exploited also. When the object is destroyed the associated processes terminate.

In the latter approach two different kinds of entities are defined, objects and processes. A process is not bound to a single object, but it is used to perform all the operations required to satisfy an action. Therefore, a process can execute within many objects changing its address space when an invocation to another object is made.

Parallel object-oriented languages use one of these two approaches to support parallel execution of object-oriented programs. Examples of languages that adopted the first approach are ABCL/1, the Actor model, Charm++ , and Concurrent Aggregates (Chien and Dally, 1990). In particular, the Actor model is the best-known example of this approach. Although it is not a pure object-oriented model, we include the Actor model because it is tight related to object-oriented languages.

On the other hand, languages like HPC++ , Argus, Presto, Nexus, Scala, and Java use the second approach. In this case, languages provide mechanisms for creating and control multiple processes external to the object structure. Parallelism is implemented on top of the object organization and explicit constructs are defined to ensure object integrity.

HPC++

High Performance C++ (Diwan and Gannon, 1999) is a standard library for parallel programming based on the C++ language. The HPC++ consortium consists of people from research groups within Universities, Industry and Government Labs that aim to build a common foundation for constructing portable parallel applications as alternative to HPF. HPC++ is composed of two levels:

- Level 1 consists of a specification for a set of class libraries based on the C++ language.
- Level 2 provides the basic language extensions and runtime library needed to implement the full HPC++ .

There are two conventional modes of executing an HPC++ program. The first is *multi-threaded shared memory* where the program runs within one context. Parallelism comes from the parallel loops and the dynamic creation of threads. This model of programming is very well suited to modest levels of parallelism. The second mode of program execution is an *explicit SPMD model* where n copies of the same program are run on n different contexts. Parallelism comes from parallel execution of different tasks. This mode is well suited for massively parallel computers.

Distributed Programming in Java

Java is an object-oriented language that was born for distributed computing programming, although it embodies a shared-memory parallel programming model discussed in Section "Shared Memory Languages". To develop parallel distributed programs using Java, a programmer can use two main approaches:

- *sockets*: at the lowest programming level, Java provides a set of socket-based classes with methods (socket APIs) for inter-process communications using *datagram* and *stream* sockets. Java sockets classes offer a low-level programming interface that requires the user to specify inter-process communication details, however this approach offers an efficient communication layer.

- *RMI*: the Remote Method Invocation toolkit ([Sun Microsystems, 1997](#)) provides a set of mechanisms for communication among Java methods that reside on different computers having separate address spaces. The approach offers a user a higher programming layer that hides some inter-process communication details, but it is less efficient compared with the socket APIs.

In the latest years several efforts have been done to extend Java for high performance scientific applications. The most significant effort is represented by the *Java Grande* consortium that aimed at defining Java extensions for implementing computing intensive applications on high performance machines. The outcome of several research projects on the use of Java for distributed memory parallel computing are a set of languages and tools such as: *HPJava*, *MPIJava*, *JMPI*, *JavaSpace*, *jPVM*, *JavaPP*, and *JCSP*.

Composition Based Languages

This section describes novel models and languages for parallel programming that have properties that make them of interest. Some are not yet extensively used but they are very interesting high-level languages. The general trend that is observable in these languages, to those discussed in the previous sections, is that they are designed with stronger semantics directed towards software construction and correctness. There is also a general realization that the level of abstraction provided by a parallel programming language should be higher than was typical of languages designed in the past decade. This is no doubt partly due to the growing role of parallel computation as a methodology for solving problems in many application areas.

The languages described in this section can be divided into two main classes:

- Languages based on predefined structures that have been chosen to have good implementation properties or that are common in applications (*restricted computation forms* or *skeletons*);
- Languages that use a *compositional* approach – a complex parallel program can be written by composing simple parallel programs while preserving the original properties.

Skeletons are predefined parallel computation forms that embody both data- and control-parallelism. They abstract away from issues such as the number of processors in the target architecture, the decomposition of the computation into processes, and communication by supporting high-level *structured parallel programming*. However, using skeletons cannot be wrote arbitrary programs, but only those that are compositions of the predefined structures. The most used skeletons are *geometric*, *farm*, *divide&conquer*, and *pipeline*. Examples of skeleton languages are *SCL*, *SkieCL*, *BMF (Bird-Meertens formalism)*, *Gamma*, and *BSPlib*.

BSPlib

The Bulk Synchronous Parallel (BSP) model is not a pure skeleton model, but it represents a related approach in which the structured operations are single threads ([Skillicorn et al., 1997](#)). Computations are arranged in *supersteps*, each of which is a collection of these threads. A superstep does not begin until all of the global communications initiated in the previous superstep have completed (so that there is an implicit barrier synchronization at the end of each superstep). Computational results are available to all processes after each superstep. The *Oxford BSPlib* is a toolkit that implements the BSP operations in C and Fortran programs ([Hill et al., 1998](#)). Some examples of BSPlib functions are.

- *bsp_init(n)* to execute *n* processes in parallel,
- *bsp_sync* to synchronize processes,
- *bsp_push_reg* to make a local variable readable by other processes,
- *bsp_put* and *bsp_get* to get and put data to/from another process,
- *bsp_bcast* to send a data towards *n* processes.

The BSPlib provides automatic process mapping and communication patterns. Furthermore, it offers performance analysis tools to evaluate costs of BSP programs on different architectures. This feature is helpful in the evaluation of performance portability of parallel applications developed by BSP on parallel computers that are based on different computation and communication structures. BSPlib offers a minimal set of powerful constructs that make the programmer task easier than more complex models and, at the same time, it support costs estimation at compile time.

Significant examples of compositional languages are Program Composition Notation (PCN), Compositional C++, Seuss, and CYES-C++. PCN and Compositional C++, are second-generation parallel programming languages in the imperative style. Both are concerned with composing parallel programs to produce larger programs, while preserving the original properties.

Closing Remarks

Parallel programming languages support the implementation of high-performance applications in many areas: from computational science to artificial intelligence applications. However, programming parallel computers is more complex of programming sequential machines because in developing parallel software must be addressed several issues that are not present in sequential programming. Parallel processes structuring, communication, synchronization, process-to-processor mapping are problems that must be solved by parallel programming languages and tools to allows users to design complex parallel applications.

New models, tools and languages proposed and implemented in the latest years allow users to develop more complex programs with minor efforts. In the recent years we registered a trend from low-level languages towards more abstract languages to simplify the task of designers of parallel programs and several middle-level models have been designed as a trade off between abstraction and high performance. The research and development efforts presented here might bring parallel programming to the right direction for supporting a wider use of parallel computers. In particular, high-level languages will make the writing of parallel programs much easier than was possible previously and will help bring parallel systems into the general computer science community.

Introduction

In the recent years there has been a huge increase in the number of genomic and proteomic sequences to be analyzed, mostly thanks to the sharp reduction of the sequencing costs made possible by NGS technologies. Unfortunately, computer hardware costs have not kept the same reduction pace, causing an economic problem to research areas that use sequencing, i.e., the entire Life Sciences. Those aspects are well summarized in [Kahn \(2011\)](#), [Mardis \(2010\)](#), where it is envisioned that the cost of analyzing sequence data may be a factor of 100 times more than the cost of its production. Apart from some particular cases, the Bioinformatics community is used to leverage on multi-processor architectures to accelerate the solution of computational intensive problems. Indeed, multi-processor calculators are inexpensive and do not require complex programming skills to be mastered. This is the case, e.g., of a simple task of counting the number of k -mers in a set of strings, a fundamental problem in Genomics and Epigenomics (see, e.g., [Compeau et al. \(2011\)](#), [Giancarlo et al. \(2015\)](#), [Utro et al. \(2015\)](#)), that is typically solved with the use of multi-processor architectures (see e.g., [Deorowicz et al. \(2015\)](#)). However, the ability of these architectures to timely analyze and solve decreasing for several reasons. Among these, the scalability of a multi-processor architecture is inherently limited by the (relative) small number of computing cores that can physically coexist on a same calculator. In addition, the computing parallelism achievable by a multi-processor architecture is heavily constrained by the intrinsic sequential nature of both the memory and the I/O subsystems. These problems can be overcome by resorting to Big Data distributed architectures, as these solutions allow for a virtual unbound scalability while requiring a programming approach easy to master. In order to foster further development of Bioinformatics and Computational Biology distributed software systems and platforms, here a short review of this area is provided. Moreover, we also identify some desirable properties that those software systems should have and provide a corresponding evaluation of them.

Specifically, Section MapReduce Fundamentals is dedicated to a short introduction to the architectural solutions available for the solution of Bioinformatics computational intensive problems and their potential issues. Then we focus on the recent approaches based on the usage of distributed systems for Big Data computing, with a particular emphasis on the MapReduce paradigm and its Hadoop and Spark implementations. In Section Systems and Applications: Description, Analysis and Assessment, we review a representative set of some of the most significant MapReduce implementations in bioinformatics, classified according to their application domain as well as to their ability to fully exploit the potential of the distributed system used to run them. In Section Closing Remarks, we focus on the alignment-free sequence comparison, by describing the first MapReduce solution to be proposed for this problem. In addition, we provide some insights on the engineering of this solution as well as an experimental assessment of its performance.

MapReduce Fundamentals

Bioinformatics problems can frequently be solved by decomposing them into simpler problems to be processed in parallel. This motivated the design of many algorithms able to exploit the several processing units available on multi-core shared-memory architectures for the effective execution of time-consuming bioinformatics tasks. Conversely, the scalability of this approach is inherently limited by some serious architectural bottlenecks, due to the competition between memory and I/O related resources. An algorithm can be considered *scalable* when its running time is inversely proportional to the number of computing units devoted to its execution.

The mentioned limits of multi-core shared-memory architectures is bypassed by resorting to *Distributed Systems*. They are architectures composed of a set of independent computers (also called *nodes*) that communicate over a network ([Tanenbaum and Van Steen, 2007](#)) and cooperate to solve a computational problem. Theoretically, with this approach, it is possible to assemble a system with an arbitrary computational capacity, as long as the corresponding number of nodes is available (i.e., *scale out*). The scalability of the system improves over multi-core shared-memory architectures as each node can access local resources without competing with other nodes.

However, such a theoretical advantage of distributed over multi-core comes at a price: the design and the development of a distributed algorithm are often a difficult task and involves complex algorithmic and programming skills. Fortunately, the adoption of one of the programming paradigms proposed in recent years for simplifying the transition toward distributed systems alleviates the mentioned problem. Among those, MapReduce ([Dean and Ghemawat, 2004](#)) paradigm is a *de facto* standard. It is described next, together with the two main middleware systems supporting it, i.e., [Apache Software Foundation \(2016a\)](#) and [Apache Software Foundation \(2016b\)](#).

MapReduce Paradigm

MapReduce (Dean and Ghemawat, 2008) is a paradigm for the processing of large amounts of data on a distributed computing infrastructure. Assuming the input data is organized as a set of $\langle \text{key}, \text{value} \rangle$ pairs, it is based on the definition of two functions. The *map* function processes an input $\langle \text{key}, \text{value} \rangle$ pair and returns a (possibly empty) intermediate set of $\langle \text{key}, \text{value} \rangle$ pairs. The *reduce* function merges all the intermediate values sharing the same key to form a (possibly smaller) set of values. These functions are run, as tasks, on the nodes of a distributed computing framework. All the activities related to the management of the lifecycle of these tasks as well as the collection of the map function results and their transmission to the reduce functions are transparently handled by the underlying framework (*implicit parallelism*), with no burden on the programmer.

Apache Hadoop

Apache Hadoop is the most popular framework supporting the MapReduce paradigm. It allows for the execution of distributed computations thanks to the interplay of two architectural components: *Yet Another Resource Negotiator* (YARN) (Vavilapalli et al., 2013) and *Hadoop Distributed File System* (HDFS) (Shvachko et al., 2010). YARN manages the lifecycle of a distributed application by keeping track of the resources available on a computing cluster and allocating them for the execution of application tasks modeled after one of the supported computing paradigms. HDFS is a distributed and block-structured file system designed to run on commodity hardware and able to provide fault tolerance through replication of data.

A basic Hadoop cluster is composed of a single *master node* and multiple *slave nodes*. The master node arbitrates the assignment of computational resources to applications to be run on the cluster and maintains an index of all the directories and the files stored in the HDFS distributed file system. Moreover, it tracks the slave nodes physically storing the data blocks making up these files. The slave nodes host a set of *workers* (also called *Containers*), in charge of running the map and reduce tasks of a MapReduce application, as well as using the local storage to maintain a subset of the HDFS data blocks.

One of the main characteristics of Hadoop is its ability to exploit data local computing. By this term, we mean the possibility to move applications closer to the data (rather than the vice-versa). This allows to greatly reduce network congestions and increase the overall throughput of the system when processing large amounts of data. Moreover, in order to reliably maintain files and to properly balance the load between different nodes of a cluster, large files are automatically split into smaller blocks, replicated and spread across different nodes.

Anatomy of a Hadoop MapReduce Application

MapReduce applications are run on the slave nodes of an Hadoop cluster in two consecutive (and potentially overlapping) phases: the map phase and the reduce phase. While in the map phase, a map task is executed for each distinct input pair by one of the workers running on the slave nodes of the Hadoop cluster. The output pairs generated during the execution of a map task are initially stored in a temporary memory buffer. When the task ends or when this buffer gets almost full, the output pairs it contains are sorted, and then saved on local disk in partitions for later processing (*spilling* step). When starting the reduce phase, output records generated during the previous spilling step are moved to the slave nodes designated for processing that partition (*shuffle* step). Once collected all records belonging to the same partition, these are sorted (*sort* step) and processed by a worker running the reduce task.

Apache Spark

Apache Spark is a new distributed framework used mainly to support programs with in-memory computing and acyclic data-flow model. In fact, Spark can be used for applications that reuse a working set of data across multiple parallel operations (e.g., iterative algorithms) and it allows the combination of streaming and batch processing (although Hadoop can be only used for batch applications). In addition, Spark is not limited to support only the MapReduce paradigm, although it preserves all the facilities of MapReduce-based frameworks, and it can have the Hadoop as the underlining middleware.

Spark has a *master/slaves* architecture where there are three main processes: *Worker*, *Executor* and *Driver*. A worker can run on any slave node, while an executor is a service launched for an application on a worker node that runs tasks and keeps data in memory or disk storage. The driver service, instead, runs on the master node and it manages the executors using a cluster resource manager (such as the default stand-alone cluster manager, Apache Mesos or YARN). In particular, the workers create executors for the driver, and then it can run tasks in those executors. In addition, each launched application has its own executors.

The *Resilient Distributed Dataset* (in short, RDD) is the main facility of Apache Spark, which is a read-only collection of objects partitioned across a set of nodes. This feature can be used to cache data in memory across nodes and they can be reused in iterative MapReduce runs. In addition, a RDD can provide many parallel operations, for example: *reduce*, *collect* and *foreach*. Spark also provides *Datasets* and *DataFrames* facilities. A Dataset is a distributed collection of data providing an interface that combines the benefits of RDDs with those of optimized execution engine of the query language. It can be constructed from objects and then manipulated using functional transformations (e.g., *map*, *flatMap*, *filter*). A DataFrame, instead, can be seen as a Dataset arranged in columns, as the concept of table in a relational database.

Finally, Spark application can be written in Java, Scala and Python language programming.

Systems and Applications: Description, Analysis and Assessment

Description

In this section, we report a classification of bioinformatics software tools developed according to the MapReduce paradigm. The vast majority of them runs on Hadoop and some on Spark. The proposed list does not aim to be exhaustive but to be representative of the most significant contributions proposed in this field. We also consider the particular case of an ad hoc framework expressly developed for the distributed genome analysis, i.e., GATK (McKenna *et al.*, 2010).

From the qualitative point of view, the properties that are desirable and that each of the considered software must have are the following.

- (a) **Programmability (PP)**. This property means that it is possible to instruct the software to solve an input problem using its own capabilities in a programmatic way. This property is held by any application whose functions can be recalled by means of a querying or a programming language. For example the Hadoop-based BioPig (Nordberg *et al.*, 2013) tool is programmable as it is possible to use its features by means of the Pig language to solve bioinformatics problems.
- (b) **Distributed Accelerator (DA)**. When facing problems that are easy to decompose, and provided that a sequential application/library already exist for solving those problems, it is possible to develop a distributed solution by just running on the nodes of a distributed system several instances of the sequential solution. In such cases, MapReduce is useful to schedule the execution of the several instances and to combine their output. Therefore, such a wrapping allows for an acceleration of the sequential package thanks to its distributed execution. For instance, CloudBLAST (Matsunaga *et al.*, 2008) is a distributed application that works by spanning multiple copies of a well-known existing application (namely BLAST (Altschul *et al.*, 1990)) on the nodes of a Hadoop cluster.
- (c) **Original Algorithm (OA)**. In this case, the proposed solution comes from the application of a new algorithm, developed according to the MapReduce paradigm to solve a classic or new bioinformatics problem. For instance, CloudAligner (Nguyen *et al.*, 2011) has been specifically designed according to the MapReduce paradigm and then implemented in Hadoop.
- (d) **Original Engineered Algorithm (OEA)**. This property holds if the MapReduce application is developed adopting an algorithm engineering approach (Cattaneo and Italiano, 1999; Demetrescu *et al.*, 2003) which, in addition to property (c), requires the outcoming code to be profiled and tuned so to allow for a full exploitation of the hardware resources of the system used to run the application.

The software can be divided into the following categories.

1. **Frameworks and support tools for the development of Bioinformatics applications**. We have included in this category software frameworks used to develop MapReduce pipelines and programs for bioinformatics (see Table 1), e.g., processing of HTS sequence data. In addition, we have included support tools and software libraries that high-level commodity functions useful for the fulfillment of auxiliary tasks in bioinformatics applications like managing files that have a standard format in bioinformatics, such as Hadoop-BAM (Niemenmaa *et al.*, 2012).
2. **Algorithms for Single Nucleotide Polymorphism Identification**. We have included in this category software that performs SNP identification and analysis (see Table 2).
3. **Gene Expression Analysis**. We have included in this category software for gene expression analysis (see Table 3), e.g., gene set analysis for biomarker identification.
4. **Sequence Comparison**. We have included in this category software for sequence comparison based on alignments and alignment-free methods (see Table 4).

Table 1 Frameworks and support tools for the development of Bioinformatics applications

Software	PP	Distributed accelerator	OA	OEA
ADAM (Nothaft <i>et al.</i> , 2015)	Yes	No	GE	GE
BioLinux (Krampis <i>et al.</i> , 2012)	SE	SE	NO	NO
BioPig (Nordberg <i>et al.</i> , 2013)	Yes	Yes	GE	NO
Biospark (Klein <i>et al.</i> , 2016)	Yes	No	ME	ME
Cloudgene (Schönherr <i>et al.</i> , 2012)	Yes	No	NO	NO
FASTdoop (Ferraro-Petrillo <i>et al.</i> , 2017)	Yes	No	GE	GE
GATK (McKenna <i>et al.</i> , 2010)	Yes	No	GE	NO
Hadoop-BAM (Niemenmaa <i>et al.</i> , 2012)	Yes	No	GE	NO
SeqInCloud (Mohamed <i>et al.</i> , 2013)	Yes	Yes	SE	ME
SeqPig (Schumacher <i>et al.</i> , 2014)	Yes	Yes	GE	NO
SparkSeq (Wiewiórka <i>et al.</i> , 2014)	Yes	No	SE	SE

Note: With reference to the main text, the software reported in this category is classified as shown. YES indicates that the property is held, while NO indicates otherwise. Other possible values indicate to what extent the property is held: GE stands for "to a great extent", ME stands for "to a moderate extent" and SE stands for "to a small extent." 5. **Genome Assembly.** We have included in this category software for *de novo* genome assembly from short sequencing reads (see [Table 5](#)).
6. **Sequencing Reads Mapping.** We have included in this category software for mapping short reads to reference genomes (see [Table 6](#)).
7. **Additional Applications.** We have included in this category MapReduce bioinformatics applications for which there is only one implementation available (see [Table 7](#)).

Analysis and Assessment

As visible in [Tables 1–7](#) there is a large number of MapReduce distributed applications developed for solving bioinformatics problems, however, few of these have been expressly developed according to the MapReduce paradigm and even a fewer number has been engineered so to be able to take out the most from the underlying distributed systems where they are run.

(Eds.), Advances in Artificial Life, Evolutionary Computation, and Systems Chemistry. WIVACE 2016. Communications in Computer and Information Science, vol. 708. Springer.

A Case Study: Alignment-Free Sequence Comparison

[Cattaneo et al. \(2016\)](#) present a Hadoop-based framework used to compute alignment-free sequence comparison using different dissimilarity measures, such as Squared Euclidean ([Vinga and Almeida, 2003](#); [Yang and Zhang, 2008](#)), based on exact k -mers counts. Given an input collection of sequences and a user-provided implementation of a dissimilarity measure, this framework operates in two subsequent steps.

Step 1: Indexing. For each input sequence, it extracts the k -mers that occur in that sequence and that are later used to compute the dissimilarity between sequences. The map function takes as an input a pair $\langle idSeq, S \rangle$, where $idSeq$ is a unique identifier for the input sequence S . Then, for each k -mer x present in S , it outputs the pair $\langle x, (idSeq, 1) \rangle$. At the end of that task, finally, each map function communicates to the reducers the length of the sequence via the pair $\langle idSeq, |S| \rangle$. The reduce function receives by the Hadoop framework a set of pairs $\langle x, L \rangle$, where L is the list of $(idSeq, 1)$ pairs corresponding to that particular k -mer, and outputs the number of times each k -mer x appears in every input sequence. That is encoded as a record $\langle x, L' \rangle$, where L' is the mentioned statistics. In addition, it returns also the size of each sequence it processed.

Step 2: Dissimilarity Measurement. Given as input a function implementing dissimilarity measure and the output of the indexing step, this step evaluates the pairwise dissimilarity for each pair of input sequences. Given a pair $\langle x, L' \rangle$, the map function computes the partial dissimilarity for each distinct pair of sequences in L' according to the input-provided measure D . As output, the map function emits a $\langle (idSeq_A, idSeq_B, D), pdiss \rangle$ pair, where $idSeq_A$ and $idSeq_B$ are the identifiers of two input sequences, while $pdiss$ is their partial dissimilarity. The reduce function receives by the Hadoop framework a set of pairs $\langle (idSeq_A, idSeq_B, D), list\{pdiss'\} \rangle$, where $list\{pdiss'\}$ is the list of all the partial dissimilarities among the sequences with identifiers $idSeq_A$ and $idSeq_B$, with respect to the measure D , and returns the pair $\langle (idSeq_A, idSeq_B, D), diss \rangle$, where $diss$ is the final value of D with respect to these two sequences.

Optimizations

Although being correct, the straightforward implementation of the Hadoop algorithm described in Section A Case Study: Alignment-Free Sequence Comparison suffered from some main performance issues when run on very long sequences. To alleviate some of these problems, the authors presented some significant optimizations:

Incremental in-mapper combining

The map tasks in the Indexing step use a hash table data structure to maintain a local index of the k -mers found while scanning an input sequence with their associated frequencies. Thanks to this optimization, the execution of a map task will produce just one single bulk output at the end of computation, including all the output pairs, rather than return a myriad of single pairs, one for each k -mer found, as required by the original implementation. As a further advantage, the overall number of output pairs of a map task will be significantly reduced because all occurrences of the same k -mer will be aggregated in a single output pair.

Input split strategies

The map tasks implement an optimized input split strategy able to manage very long multi-line sequences during the Indexing step. It works by splitting an input sequence S , encoded as a FASTA file, in several records $\langle id_S, (S_i, S_{i+1}) \rangle$, where id_S is an identifier for S , S_i is the i -th row of S and S_{i+1} contains the first $k-1$ characters of the $(i+1)$ -th row of S (S_{i+1} is empty if i is the last row of S). Differently from the standard Hadoop input strategies, this optimization allows each map task run during the Indexing step to extract autonomously all the k -mers that originate from a particular row of the input file thus allowing the processing of sequences of arbitrary length while exploiting the implicit parallelism available with Hadoop.

Experimental Analysis

The Hadoop-based framework presented in Section A Case Study: Alignment-Free Sequence Comparison has been subject to an experimental analysis aimed at assessing its ability to scale with the number of computing units devoted to its execution as well as its capacity to increase the span of the problems that can be solved with respect to the sequential approach. To this end, the authors used a dataset coming from meta-genomic studies, e.g., [Huang et al. \(2013a,b\)](#), and including all the sequenced microbial genomes (bacteria, archaea, viruses) available in public databases. It consists of 40,988 genomes, for a total of 172 GB.

The experiments have been conducted on a homogeneous cluster of 4 slave nodes and a master node, equipped each with 32 GB of RAM, 2 AMD Opteron @ 2.10 GHz processors, 1 TB disk drive and a Giga-Ethernet network card. A HDFS replication factor set to 2 and a block size set to 128 MB have been used.

The dataset has been processed by measuring the time required to evaluate the Squared Euclidean dissimilarity measure with $k=12$. Let S and Q be two sequences, this measure ([Vinga and Almeida, 2003](#); [Yang and Zhang, 2008](#)) evaluates their dissimilarity as:

$$d_{SE}(S, Q) = \sum_{i=1}^n (s_i - q_i)^2 \quad (1)$$

where s_i and q_i are the number of occurrences of the i -th k -mer in S and in Q , respectively.

During the tests, the authors measured the scalability of the proposed framework by increasing the number of CPU cores that are reserved to the cluster and, consequently, the number of map/reduce tasks that are run concurrently, while keeping fixed the input dataset. The outcoming performance have then been compared with those of the sequential version of the same algorithm. The overall results are reported in [Figs. 1 and 2](#), where it is also indicated the time spent for steps 1 and 2, respectively.

Fig. 1 Elapsed times for evaluating the Squared Euclidean dissimilarity measure among 60 sequences extracted from the dataset with a total size of $\approx 600,000,000$ characters, with $k=12$ and an increasing number of concurrent map/reduce tasks, using both the naive and improved versions of our distributed paradigm. Reproduced from Cattaneo, G., Ferraro Petrillo, U., Giancarlo, R., Roscigno, G., 2016. An effective extension of the applicability of alignment-free biological sequence comparison algorithms with Hadoop. *The Journal of Supercomputing* 1–17.

Fig. 2 Elapsed times for evaluating the Squared Euclidean dissimilarity measure among 60 sequences extracted from the dataset with a total size of $\approx 600.000.000$ characters, with $k=12$ and an increasing number of concurrent map/reduce tasks. For completeness, we also report the time of the sequential algorithm. Reproduced from Cattaneo, G., Ferraro Petrillo, U., Giancarlo, R., Roscigno, G., 2016. An effective extension of the applicability of alignment-free biological sequence comparison algorithms with Hadoop. *The Journal of Supercomputing* 1–17.

Results and Discussion

We have presented a review of some of the most significant MapReduce bioinformatics applications. The increasing number and the quality of the contributions proposed in this field show the arising interest toward the use of Distributed Computing, and of its popular MapReduce computing paradigm, for the solution of computational intensive bioinformatics problems. However, as witnessed by experiences like the ones documented in Cattaneo *et al.* (2016), Bertoni *et al.* (2015), an effective exploitation of the computation resources available with a distributed system can only be achieved through an accurate engineering activity of the MapReduce algorithms as well as a careful choice of the underlying software framework and support tools.

Closing Remarks

We have presented the state of the art regarding the use of Distributed Computing, in particular, software designed with MapReduce paradigm, in Bioinformatics and Computational Biology. Although such a body of work will grow in the future, it would be appropriate to follow good design and algorithm engineering approaches in order to use in full the available hardware and the scalability MapReduce offers.

Acknowledgement

We would like to thank the Department of Statistical Sciences of University of Rome – “La Sapienza”, for computing time on the TeraStat supercomputing cluster. Moreover, the authors are also grateful to the Consortium GARR for having made available a cutting-edge OpenStack Virtual Datacenter which will turn out to be instrumental in the continuation of this research that tries to establish the impact that MapReduce can have on bioinformatics research.

Infrastructure for High-Performance Computing: Grids and Grid Computing

Ivan Merelli, Institute for Biomedical Technologies (CNR), Milan, Italy and National Research Council, Segrate, Italy

Introduction

The lightening development of molecular biology techniques, with the increased capacity of producing high-throughput experiments, is posing important challenges for data storage, organization and analysis in Computational Biology and Bioinformatics. Handling the vast quantities of biological data generated by high-throughput experimental technologies is becoming increasingly difficult in a localized environment.

Small companies and small research groups produce uneven spikes of computationally intensive jobs, which makes a privately owned IT infrastructure a non-effective solution, since clusters can be underpowered during the actual spikes of work, while remaining underused for the majority of the time. Moreover, local clusters tend to be very expensive, since beside the hardware and software costs, electricity and cooling systems, the personnel for administration should also be considered.

Accordingly, Bioinformatics is experiencing a new trend in the way analysis is performed: computation is moving from in-house computing infrastructure to distributed computing delivered over the Internet. In this context, grid technology is a very interesting solution (Talbi and Zomaya, 2007), since it permits the transparent coupling of geographically dispersed resources (machines, networks, data storage, visualization devices, and scientific instruments) for large-scale distributed applications.

Starting from 2000s, grid computing has been for many years a resource of computational power suitable to support bioinformatic researches. Although developed in the field of high energy physics, the biomedical and bioinformatic communities worked as testbed of the infrastructure and many computational challenges have been performed. Beside large campaigns for the analysis of bio-sequences (Trombetti *et al.*, 2007), grid computing has been widely exploited in structural Bioinformatics, both for large scale virtual screenings, challenges of drugs discovery for neglected diseases (Lee *et al.*, 2006; Jacq *et al.*, 2007) and molecular dynamics of huge biomolecular systems (Merelli *et al.*, 2007).

The problem with grid computing is the low flexibility of the infrastructure, since there is only limited access to the servers, with little or no interactivity, due to remote batch scheduling of the jobs on the remote clusters. For desktop-based grid infrastructures the situation is even worst (Fedak, 2012). The management of the distributed data storage is very complex, not to mention the administration of geographically dispersed databases. The grid environment should be perfectly tuned in order to make an application running: a classical example is the presence of a mis-configured node on the grid, in which jobs fail continuously, emptying the grid queue, an effect known as *shrink-hole*.

More recently, grid computing embraced the idea of virtualization, moving towards a cloud computing paradigm. Different paradigms are available to implement this approach (Kee and Kesselman, 2008). This virtualization layer allows more flexibility, making grid computing able to address Big Data problems in many fields of Bioinformatics. For example, the Worker Nodes on Demand Service (WNoDeS) is a framework that makes possible to dynamically allocate virtual resources out of a common resource pool (Salomoni *et al.*, 2011).

Which Bioinformatic Applications Need Distributed Computing?

Considering bio-sequence analysis, short-read from Next-Generation Sequencing can be easily aligned against a reference genome on a single server using multi-thread implemented applications, such as Bowtie (Langmead and Salzberg, 2012). But the large number of experiments that are daily performed to identify genomic and epigenomic variations in patients affected by different diseases, and in particular cancer (which also requires a specific annotation of data; Alfieri *et al.*, 2008), generates huge computational loads, which boosted the development of grid tools to face this problem (Luyf *et al.*, 2010).

Nonetheless, more sophisticated analysis can be necessary from time to time. For example, to align protein or nucleic sequences against protein databases researchers must use tools such as BLAST (Altschul *et al.*, 1997), which has been ported in grid using many different approaches, such as BeoBlast (Grant *et al.*, 2002), Soap-HT-BLAST (Wang and Mu, 2003), mpiBLAST (Darling *et al.*, 2003), GridBLAST (Krishnan, 2005), ND-BLAST (Dowd *et al.*, 2005) and BGBlast (Trombetti *et al.*, 2007), and Crossbow (Gurtowski *et al.*, 2012).

Another example of sequence based analysis is the identification of regulatory patterns using HMMER (Finn *et al.*, 2011) (or similar Hidden Markov Model based software), which has been also ported on grid (Ciuffo and Mayo, 2009). The analysis of microRNA targets is also very complex, because the identification relies both on sequence similarity and on thermodynamic considerations (Ronchieri *et al.*, 2016). Moreover, microRNA seed sequences are very short, which contributes at generating a huge number of target predictions, also considering that the binding between the microRNA and the gene can have mismatches, at least in animals.

Huge efforts are also necessary to understand the impact of genome variations in the development of diseases. Genome wide association studies, involving thousands of patients, are routinely performed to discover possible biomarkers and design new

therapies (Merelli *et al.*, 2013). This requires large computational effort to achieve accurate statistical testing and Plink (Purcell *et al.*, 2007), which is one of the most used software for this kind of analysis, has been also ported to grid (Calabria *et al.*, 2010).

However, the most time consuming applications from the biological domain are those related to structural Bioinformatics (Chiappori *et al.*, 2013). Drug discovery and design are highly computational intensive, because large datasets of chemical compounds must be tested against molecular targets (usually proteins) to find molecules that can act as drugs. Considering that docking software are usually optimized for specific target families, it is usually a good idea to test many of them (Morris *et al.*, 2009; Mukherjee *et al.*, 2010; Friesner *et al.*, 2006; Merelli *et al.*, 2011). This approach, sometimes referred as virtual screening, requires massive computational resources, but it is very precious to reduce the number of wet experiments to perform, in particular for neglected diseases (D'Agostino *et al.*, 2013).

Moreover, side effects caused by off-target bindings should be avoided, therefore the most promising compounds are usually tested against many other proteins. At last, the docking conformations that describe the interactions between the compound and the targets should be optimized through molecular dynamics simulations to relax the system and improve the accuracy by which the binding energy is calculated. Molecular dynamics is a physical simulations in which the Newton's equations of motions are solved for each atom of the systems considering all the forces involved in the interaction (Merelli *et al.*, 2007) and, depending on the number of involved atoms, it can be very computationally demanding. Many attempts have been made to perform molecular dynamics on grid (Chiappori *et al.*, 2012, 2016), by using different paradigms, although one of the most popular is the Hamiltonian Replica Exchange (Jiang *et al.*, 2014).

Globus Based Grids

Most of the modern grid infrastructures rely on standard implementations of a middleware, such as the Globus Toolkit (Foster, 2006), an open source software for building Grid Services (GS). On the top of this middleware different grid implementations have been proposed, which usually follow two directions. The first is mainly application oriented and uses GS to provide utilities, such as authenticated and session enabled applications, providing high portability, but low scalability (Goble *et al.*, 2003). The second is a set of blank GS, that are computational resources where both data and software must be copied to perform computations, which present high scalability, but lower portability (Burke *et al.*, 2008).

These implementations cover different aspects, which can be both useful in Bioinformatics. The first is mainly related to the accessibility of distributed services, while the second concerns the possibility to perform wide range computations. While the service oriented implementation can be useful in terms of workflow composition, which can be remotely executed on distributed resources, the added value of the grid probably relies in the second implementation, which can be effectively used to mine the huge quantity of data that molecular biology is currently producing. In the rest of the section we will discuss this second aspect, as this is highly innovative, and with a particular attention to the EGEE project grid implementation, which is becoming the de-facto standard for grid computing in Europe.

The EGEE/EGI Grid Platform

The EGEE/EGI project infrastructure is a wide area grid platform for scientific applications composed of thousands of CPUs. This platform is a network of several Computing Elements, which constitute the gateways for the computer clusters on which jobs are performed, and an equal number of Storage Elements, that implement a distributed file system on which files are stored. The grid core is a set of Resource Brokers delegated for controlling submission and execution of the different jobs.

The computational resources are connected to a Resource Broker that routes each job on a specific Computing Element taking into account the directives of the submitting script, encoded using the Job Description Language (JDL), and implements a load balancing policy. Each Computing Element submits the incoming job to a batch system queue hiding many Working Nodes. A set of tools is used to manage data as in a distributed file systems. These tools allow the data to be replicated to different Storage Elements easily, and help using this information in an efficient way. The Resource Broker, in fact, is able to redirect the execution of an application to a Computing Element located as near as possible to the data being used, hence minimizing the communication time.

Apart from uploading data from the Storage Elements, a procedure that typically is reserved to large files and reference databases, in the JDL script it is possible specify an InputSandBox: a collection of files which are sent directly on the computational resources. This aspect is very important because it allows the subdivision of the input sequences to be analyzed and their direct upload with the related job to be computed. At the same way output data can be downloaded from the Working Nodes without copying data on the Storage Elements by using the OutputSandBox.

The EGEE grid enables an efficient data management, by coupling the Storage Element services, where files are stored, with the LHC File Catalogues where the physical handlers of files, which depend on the specific storage facility used, are recorder and associated to the logical file names. This system allows to have more replicas for each file, a feature that is crucial to implement redundancy of the reference databases, minimizing the transfer rate at running time. The system composed by the Storage Elements and the related LHC File Catalogue implements an effective virtual distributed file system, which allows redundancy and replicas of files.

All the elements of this grid computing environment are deployed as Grid Services, which envelope the main basic functionalities, enabling secure communications among the grid components. In particular, the gLite middleware must be installed on a local server within the institution that wants to join the EGEE grid in order to establish secure communications between the institution itself and the distributed infrastructure. This local server, which is usually called User Interface, through the gLite APIs enables to submit jobs, to monitor the state of advancement of the jobs, to retrieve the outputs when the computations have a normal termination and to resubmit the jobs in case of failure.

Due to the use of remote computational resources, the grid communication software must offer an efficient security system. Simply stated, security is guaranteed by the Grid Security Infrastructure (GSI), which uses public key cryptography to recognize users. GSI certificates are encoded in the X.509 format and accompany each job to authenticate the user. In other words, the access to remote clusters is granted by a Personal Certificate, which accompanies each job to authenticate the user. Moreover, users must be authorized to job submission by a Virtual Organization, a grid community having similar tasks, which grants for him. This procedure is indispensable for maintaining a high security level.

BIONC Based Grids

The other grid approach that gained progressive success in the scientific community is known as Desktop Grids (DGs), which often relies upon the general public to donate resources (volunteer computing). Unlike Grid Services, which are based on complex architectures, volunteer computing has a simple architecture and has demonstrated the ability to integrate dispersed, heterogeneous computing resources with simplicity, successfully scavenging cycles from tens of thousands of idle desktop computers. This paradigm represents a complementary trend concerning the original aims of Grid computing. In DG systems, anyone can bring resources into the Grid, installation and maintenance of the software is intuitive, requiring no special expertise, thus enabling a large number of donors to contribute into the pool of shared resources.

On the down-side, only a very limited user community (i.e., target applications) can effectively use Desktop Grid resources for computation. The most well-known DG example is the SETI@home ([Anderson et al., 2002](#)) project, in which approximately four million PCs have been involved. The middleware that was originally developed to support SETI@home is the Berkeley Open Infrastructure for Network Computing (BOINC, [Anderson, 2004](#)), which rapidly became a generalized platform for other distributed applications in areas as diverse as mathematics, linguistics, medicine, molecular biology, climatology, environmental science, and astrophysics, among others.

Rosetta@Home

Rosetta@home is a distributed computing project for protein structure prediction, relying on the BOINC platform, which aims at performing protein-protein docking and protein modelling. Though much of the project is oriented toward basic research to improve the accuracy and robustness of proteomic methods, Rosetta@home also does applied research on malaria, Alzheimer's disease, and other pathologies ([Das et al., 2007](#)).

Like all BOINC projects, Rosetta@home uses idle computer processing resources from volunteers' computers to perform calculations on individual workunits. Completed results are sent to a central project server where they are validated and assimilated into project databases. The project is cross-platform, and runs on a wide variety of hardware configurations. Users can view the progress of their individual protein structure prediction on the Rosetta@home screen saver.

In addition to disease-related research, the Rosetta@home network serves as a testing framework for new methods in structural Bioinformatics. Such methods are then used in other Rosetta-based applications, like RosettaDock and the Human Proteome Folding Project, after being sufficiently developed and proven stable on Rosetta@home's large and diverse set of volunteer computers. Two especially important tests for the new methods developed in Rosetta@home are the Critical Assessment of Techniques for Protein Structure Prediction (CASP) and Critical Assessment of Prediction of Interactions (CAPRI) experiments, biannual experiments that evaluate the state of the art in protein structure prediction and protein-protein docking prediction, respectively. Rosetta@home consistently ranks among the foremost docking predictors, and is one of the best tertiary structure predictors available ([Lensink et al., 2007](#)).

Virtual Paradigms

The main distinguishing feature between GSs and DGs is the way computations are initiated at the grid resources. In Grid Services a job submission or a service invocation is used to initiate the activity on a grid resource. Both can be considered as a specific form of the *push model* where the service requestor pushes jobs, tasks, service invocations on the passive resources.

Once such a request is pushed on the resource, it becomes active and the requested activity is executed. Desktop Grids work according to the *pull model*. Resources that have got spare cycles pull tasks from the application repository, which is typically placed on the DG server. In this way resources play an active role in the DG system, they initiate their own activity based on the task pulled from the server.

Both these approaches are quite rigid and can suffer from mis-configuration of the resources, which may cause many job failure. To solve this problem and implement a more interactive paradigm, grid computing has recently moved towards the idea of virtualization. The possibility to virtualize resources is critical for making grid computing able to address the complex workflow analysis systems that are necessary in Bioinformatics.

One of the most interesting approaches in this sense is Worker Nodes on Demand Services (WNoDes) framework (Salomoni *et al.*, 2011), which implement a Cloud over grid approach. It provides a cloud-based environment by instantiating resources on top of a grid infrastructure. WNoDes instantiates virtual machines from predefined images on top of Grid resources exploiting the local batch system of the grid site. Other examples are the CLEVER project (Tusa *et al.*, 2010), which supplies access to private and hybrid cloud, and PerfCloud (Mancini *et al.*, 2009), a novel architecture that creates configurable virtual clusters to be used in the grid environment.

The above mentioned paradigm can be exploited both through services and software frameworks, such as the distributed infrastructure with remote agent control (DIRAC, Fifield *et al.*, 2011), HTCondor (Thain *et al.*, 2006) and the gLite workload management system (Marco *et al.*, 2009), which are able to provide high-level job submission services as front end, and the possibility to interact with heterogeneous systems at the back end. In particular, the gLite WMS and DIRAC provides a complete solution to one (or more) user community requiring access to distributed resources. HTCondor supports distributed parallelised jobs on grid and cloud resources.

Performance

A critical point to justify the effort required for porting a bioinformatic application over grid is the possibility to achieve good performance. Clearly, scalability results are very important while considering the grid infrastructure as a possible solution to reduce the time required for a computation. In particular, we would discuss the job efficiency and the latency time, which are critical to decide the granularity of the computation, the overhead imposed by the grid and the global scalability of the infrastructure.

Job Efficiency and Latency Time

In literature are reported different analyses of the grid efficiency (Merelli *et al.*, 2015), which for bioinformatic applications seem to settle around the 70% of the jobs reported as successfully finished according to the status logged in the Resource Broker. A ratio that goes down to 60% after checking the existence of the output (Merelli *et al.*, 2015). The main cause of job failure seems to be the data transfer between the Storage Elements and the Computing Elements and, in few cases, the communication between the Computing Elements and the local results database.

This can be inferred by the differences in the statistics achieved by different computational challenges: challenges in which the data transfer rate is relatively important present a higher number of failures (Merelli *et al.*, 2015). Another frequent problem is related to errors during the job scheduling: a very high ratio of these failures came from the mis-configuration of Computing Elements. On the other hand, the number of jobs reported as correctly finished by the grid, but resubmitted because the results didn't match with the expected information is generally pretty low.

A very important factor for the reliability of the grid is the average latency time, which can be defined as the sum of the time spent for establishing communication with the Resource Broker and the scheduling time on the Computing Element queue. Depending on the average load of the grid, and considering only jobs that come to completion at the first round, the average latency time can be estimated in a few hours (Merelli *et al.*, 2015). Clearly this latency time has low impact on long term jobs, but heavily influences short jobs, making the grid quite unsuitable for short computations.

Granularity

A key parameter for the evaluation of the distribution of the computational load is the estimated duration of a single grid job. Apart from job failures due to data transfer or internal errors, the time needed for completing the whole computation can also be elongated by the execution of jobs too short, which greatly increase the latency in the execution queue. On the other hand the submission of a small number of jobs limits the scalability of the system and in case of failure may impose to wait long time for the fulfilment of a few resubmitted jobs. Hence, the length of the submitted jobs should be carefully planned.

Crunching Factor

Defining the scalability of a grid infrastructure is not easy as for parallel infrastructure, since it is not possible to compute the speed-up of an application. Nonetheless, in the grid domain, it is possible to estimate the crunching factor, which is defined as the expected single-core time required for the computational divided by the real computational time achieved on the distributed platform. This is the time needed to complete the last job. The CPU utilization peak is usually much higher, but due to overhead caused by queuing for accessing grid resources and job failures the scalability is generally lower. To avoid this problem, commonly named *last job syndrome*, it is possible to submit multiple replicas of the jobs that failed at the first round. Once the fastest replica is finished for each job failed at the first round, all the remaining computations can be dropped, which usually is a useful trick to accelerate the computation and improve the crunching factor.

Conclusions

In the last years, the role of grid computing has become increasingly important in scientific research. Concerning Bioinformatics, grid computing tackles challenges of processing power, large-scale data access and management, security, application integration, data integrity and curation, control/automation/tracking of workflows, data format consistency and resource discovery.

Grid technology allows computational intensive challenges to be accomplished, but due to its rigid constraints a capable submission and monitoring environment should be set-up in order to appropriately manage the volume of data. To mitigate these problems, where possible, the creation of a flexible virtual environment can play an important role to achieve good results in short time.

In conclusion, the grid is an effective system for coping with the increasing demand of computational power in Bioinformatics. The system scalability in case of independent computations is very high, even taking into account the time needed for scheduling jobs and transferring data. Such computing power is a concrete possibility to face challenges that have been thought to be impossible just few years ago.

Infrastructures for High-Performance Computing: Cloud Computing

Paolo Trunfio, University of Calabria, Rende, Italy

© 2019 Elsevier Inc. All rights reserved.

Introduction

Cloud Computing abstracts computing resources to a utility-based model. This model is based on the virtualization of networks, servers, storage and services that clients can allocate on a *pay-per-use* basis to implement their distributed applications. From a client perspective, the cloud is an abstraction for remote, infinitely scalable provisioning of computing resources. From an implementation point of view, cloud systems are based on large sets of computing resources, located somewhere “in the cloud”, which are allocated to applications on demand (Barga *et al.*, 2011).

Thus, cloud computing can be defined as a distributed computing paradigm in which all the resources, dynamically scalable and virtualized, are provided as services over the Internet (Talia *et al.*, 2015). Virtualization is software-based technique that implements the separation of physical computing infrastructures and allows creating various “virtual” computing resources on the same hardware. It is a basic technology that powers cloud computing by making possible to concurrently run different operating environments and multiple applications on the same server. Differently from other distributed computing paradigms, cloud users are not required to have knowledge of, expertise in, or control over the technology infrastructure in the “cloud” that supports them. A number of features define cloud applications, services, data, and infrastructure:

- Remotely hosted: Services and/or data are hosted on remote infrastructure.
- Ubiquitous: Services or data are available from anywhere.
- Pay-per-use: The result is a utility computing model similar to that of traditional utilities, like gas and electricity, where you pay for what you use.

We can also refer to the popular National Institute of Standards and Technology (NIST) definition of cloud computing to highlight its main features (Mell and Grance, 2011): “Cloud computing is a model for enabling convenient, on-demand network access to a shared pool of configurable computing resources (e.g., networks, servers, storage, applications, and services) that can be rapidly provisioned and released with minimal management effort or service provider interaction”. From the NIST definition, we can identify five essential characteristics of cloud computing systems:

1. *On-demand self-service*: The ability to allocate resources on-demand and through self-service interfaces.
2. *Broad network access*: The availability of high speed network access to all of the resources.
3. *Resource pooling*: A common pool of resources is transparently allocated to multiple users.
4. *Rapid elasticity*: The ability to scale up or scale down in the shortest possible time.
5. *Measured service*: The ability to control the use of resources by leveraging a resource metering system.

Cloud systems can be classified on the basis of their *service model* (Software as a Service, Platform as a Service, Infrastructure as a Service) and their *deployment model* (public cloud, private cloud, community cloud).

Service Models

Cloud computing vendors provide their services according to three main models: Software as a Service (SaaS), Platform as a Service (PaaS), and Infrastructure as a Service (IaaS).

Software as a Service defines a delivery model in which software and data are provided through Internet to customers as ready-to-use services. Specifically, software and associated data are hosted by providers, and customers access them without need to use any additional hardware or software. Moreover, customers normally pay a monthly/yearly fee, with no additional purchase of infrastructure or software licenses. Examples of common SaaS applications are Webmail systems (e.g., Gmail), calendars (Yahoo Calendar), document management (Microsoft Office 365), image manipulation (Photoshop Express), customer relationship management (Salesforce), and others.

In *Platform as a Service* model, cloud vendors deliver a computing platform typically including databases, application servers, development environment for building, testing and running custom applications. Developers can just focus on deploying of applications since cloud providers are in charge of maintenance and optimization of the environment and underlying infrastructure. Hence, customers are helped in application development as they use a set of “environment” services that are modular and can be easily integrated. Normally, the applications are developed as ready-to-use SaaS. Google App Engine, Microsoft Azure, Salesforce.com are some examples of PaaS cloud environments.

Finally, *Infrastructure as a Service* is an outsourcing model under which customers rent resources like CPUs, disks, or more complex resources like virtualized servers or operating systems to support their operations (e.g., Amazon EC2, RackSpace Cloud). Users of an IaaS have normally skills on system and network administration as they must deal with configuration, operation and

maintenance tasks. Compared to the PaaS approach, the IaaS model has a higher system administration costs for the user; on the other hand, IaaS allows a full customization of the execution environment. Developers can scale up or down its services adding or removing virtual machines, easily instantiable from a virtual machine images.

In the following we describe how the three service models satisfy the requirements of developers and final users, in terms of *flexibility, scalability, portability, security, maintenance* and *costs*.

Flexibility

SaaS: Users can customize the application interface and control its behavior, but cannot decide which software and hardware components are used to support its execution.

PaaS: Developers write, customize, test their application using libraries and supporting tools compatible with the platform. Users can choose what kind of virtual storage and compute resources are used for executing their application.

IaaS: Developers have to build the servers that will host their applications, and configure operating system and software modules on top of such servers.

Scalability

SaaS: The underlying computing and storage resources normally scale automatically to match application demand, so that users do not have to allocate resources manually. The result depends only on the level of elasticity provided by the cloud system.

PaaS: Like the SaaS model, the underlying computing and storage resources normally scale automatically.

IaaS: Developers can use new storage and compute resources, but their applications must be scalable and allow the dynamic inclusion of new resources.

Portability

SaaS: There can be problems to move applications to other providers, since some software and tools could not work on different systems. For example, application data may be in a format that cannot be read by another provider.

PaaS: Applications can be moved to another provider only if the new provider shares with the old one the required platform tools and services.

IaaS: If a provider allows to download a virtual machine in a standard format, it may be moved to a different provider.

Security

SaaS: Users can control only some security settings of their applications (e.g., using https instead of http to access some Web pages). Additional security layers (e.g., data replication) are hidden to the user and managed directly by the system.

PaaS: The security of code and additional libraries used to build application is responsibility of the developer.

IaaS: Developers must take care of security issues from operating system to application layer.

Maintenance

SaaS: Users have not to carry maintenance tasks.

PaaS: Developers are in charge of maintaining only their application; other software components and the hardware are maintained by the provider.

IaaS: Developers are in charge of all software components, including the operating system; hardware is maintained by the provider.

Cost

SaaS: Users typically pay a monthly/yearly fee for using the software, with no additional fee for the infrastructure.

PaaS: Developers pay for the compute and storage resources, and for the licenses of libraries and tools used by their applications.

IaaS: Developers pay for all the software and hardware resources used.

Deployment Models

Cloud computing services are delivered according to three main deployment models: public, private and community cloud.

A *public cloud* provider delivers services to the general public through the Internet. The users of a public cloud have little or no control over the underlying technology infrastructure. In this model, services can be offered for free, or provided according to a *pay-per-use* policy. The main public providers, such as Google, Microsoft, Amazon, own and manage their proprietary data centers delivering services built on top of them.

Fig. 1 General architecture of a public cloud.

A *private cloud* provider offers operations and functionalities “as a service”, which are deployed over a company intranet or hosted in a remote data center. Often, small and medium-sized IT companies prefer this deployment model as it offers advance security and data control solutions that are not available in the public cloud model.

A *community cloud* is a model in which the infrastructure is provisioned for reserved use of a given community of organizations that have shared objectives and requirements. This kind of cloud may be owned and managed by one or more of the organizations in the community, or by an organization that is not part of the community, or some combination of them.

Fig. 1 depicts the general architecture of a public cloud and its main components, as outlined in [Li et al. \(2010\)](#) and [Talia et al. \(2015\)](#). Users access cloud computing services using *client* devices, such as desktop computers, laptops, tablets and smartphones. Through these devices, users access and interact with cloud-based services using a Web browser or desktop/mobile app. The business software and user’s data are executed and stored on servers hosted in cloud data centers that provide *storage and computing resources*. Resources include thousands of servers and storage devices connected each other through an *intra-cloud network*. The transfer of data between data center and users takes place on *wide-area network*.

Several technologies and standards are used by the different components of the architecture. For example, users can interact with cloud services through SOAP-based or RESTful Web services ([Richardson and Ruby, 2007](#)). *HTML5* and *Ajax* technologies allow Web interfaces to cloud services to have look and interactivity equivalent to those of desktop applications. *Open Cloud Computing Interface* (OCCL, OCCI Working Group, see Relevant Websites section) specifies how cloud providers can deliver their compute, data, and network resources through a standardized interface. Another example is *Open Virtualization Format* (OVF, OVF Specification, see Relevant Websites section) for packaging and distributing virtual devices or software (e.g., virtual operating system) to be run on virtual machines.

Interconnected Clouds

Interconnection and interoperability of different clouds can be beneficial to both cloud providers and their clients for avoiding vendor lock-in, to increase scalability and availability, to reduce access latency, and to improve energy efficiency ([Toosi et al., 2014](#)). Interoperability between clouds can be obtained through either *provider-centric* or *client-centric* approaches. With a provider-centric approach, cloud providers adopt and implement standard interfaces, protocols, formats, and architectural components that facilitate collaboration between different clouds. With a client-centric approach, there is a user-side library or a third-party service broker that translates messages between different cloud interfaces, thus allowing clients to switch between different clouds.

The most important provider-centric approaches are *hybrid cloud*, *cloud federation*, and *Inter-cloud*:

- A *hybrid cloud* is the composition of two or more (private or public) clouds that remain different entities but are linked together. Companies can extend their private clouds using other private clouds from partner companies, or public clouds. In particular,

by extending the private infrastructure with public cloud resources, it is possible to satisfy peaks of requests, better serve user requests, and implement high availability strategies.

- A *cloud federation* allows providers to overcome resource limitation in their local cloud infrastructure, which may result in refusal of client requests, by outsourcing requests to other members of the federation. This is made by sharing the cloud resources through federation regulations, which allows providers operating at low utilization rates to lease part of their resources to other members of the federation, thus improving resource utilization and reducing costs.
- An *Inter-cloud*, or *cloud of clouds*, is a model in which all clouds are globally interconnected, forming a global cloud federation. This approach removes difficulties related to the migration of applications and supports their dynamic scaling across multiple clouds worldwide.

Client-centric interoperability approaches can be classified into *multicloud* and *aggregated service by broker* models:

- In the *multicloud* model, the client applications are run on several clouds with the help of a user-side library, thus avoiding the difficulty of migrating applications across clouds.
- In the *aggregated service by broker*, a third-party broker offers an integrated service to users by coordinating access and utilization of multiple cloud resources.

As discussed in Toosi *et al.* (2014), cloud interoperability is still a challenging issue that requires substantial efforts to overcome the existing functional and nonfunctional problems in important areas such as security, virtualization, networking and provisioning.

Closing Remarks

In this article we provided an overview of cloud computing concepts and models. Starting from the NIST definition of cloud computing, we discussed the main features of cloud systems, and analyzed the most important service models (Software as a Service, Platforms as a Service, Infrastructure as a Service) and deployment models (Private Cloud; Community Cloud; Public Cloud) currently adopted by cloud providers. Finally, we discussed the most important models for the interconnection and interoperability of cloud environments (Hybrid Cloud, Cloud Federation, and Inter-cloud).

Infrastructures for High-Performance Computing: Cloud Infrastructures

Fabrizio Marozzo, University of Calabria, Rende (CS), Italy

© 2019 Elsevier Inc. All rights reserved.

Introduction

This article describes the main services provided by the most popular cloud infrastructures currently in use. The systems presented in this article are either public clouds *Amazon Web Services (AWS)*, *Google Cloud Platform*, *Microsoft Azure* and *IBM Bluemix* or private clouds *OpenStack*, *OpenNebula* and *Eucalyptus*.

All the public cloud systems provide services according to the Infrastructure as a Service (IaaS), Platform as a Service (PaaS) and Software as a Service (SaaS) models (Talía et al., 2015). With the IaaS model, the cloud system provide services that allow customers to rent virtualized resources like storage and servers; the PaaS model allows developers to focus on deploying of applications, since cloud providers are in charge of managing the underlying infrastructure; with the SaaS model, software and data are provided to customers as ready-to-use services.

As examples of IaaS services, AWS provides the popular *Elastic Compute Cloud (EC2)* service that allows creating and running virtual servers; Google Cloud Platform allows developers to run virtual machines through its *Compute Engine* service; Microsoft Azure provides a *VM role* service to manage virtual-machine images; IBM Bluemix *Virtual servers* can be used to deploy and scale virtual machines on demand.

As examples of PaaS services, AWS provides *Elastic Beanstalk* to create, deploy, and manage applications using a large set of infrastructure services; Google Cloud Platform includes *App Engine*, a PaaS that allows developers to create and host web applications in Google-managed data centers; Microsoft Azure's PaaS includes a *Web role* for developing Web-based applications and a *Worker role* for batch applications; IBM Bluemix includes *Mobile Foundation*, a set of APIs to manage the life cycle of mobile applications.

Finally, some examples of SaaS services are *Simple Email Service (AWS)*, *Gmail (Google Cloud Platform)*, *Office 365 (Microsoft Azure)* and *Natural Language Understanding (IBM Bluemix)*.

In general, the private cloud systems are more focused on the IaaS model, as they provide services for the management of large pools of processing, storage, and networking resources in a data center, by exploiting a variety of virtualization techniques. For example, OpenStack with its *Compute* component provides virtual servers and with its *Storage* component provides a scalable and redundant storage system; OpenNebula's *Core component* creates and controls virtual machines by interconnecting them with a virtual network environment; Eucalyptus includes a *Node Controller* that hosts the virtual machine instances and manages the virtual network endpoints, and a *Storage Controller* that provides persistent block storage and allows the creation of snapshots of volumes.

Amazon Web Services

Amazon offers compute and storage resources of its IT infrastructure to developers in the form of Web services. Amazon Web Services (AWS) is a large set of cloud services that can be composed by users to build their SaaS applications or integrate traditional software with cloud capabilities (see Fig. 1). It is simple to interact with these services since Amazon provides SDKs for the main programming languages and platforms (e.g., Java, .Net, PHP, Android).

AWS includes the following main services:

- Compute: *Elastic Compute Cloud (EC2)* allows creating and running virtual servers; *Amazon Elastic MapReduce* for building and executing MapReduce applications.
- Storage: *Simple Storage Service (S3)*, which allows storing and retrieving data via the Internet.
- Database: *Relational Database Service (RDS)* for relational tables; *DynamoDB* for non-relational tables; *SimpleDB* for managing small datasets; *ElasticCache* for caching data.
- Networking: *Route 53*, a DNS Web service; *Virtual Private Cloud* for implementing a virtual network.
- Deployment and Management: *CloudFormation* for creating a collection of ready-to-use virtual machines with pre-installed software (e.g., Web applications); *CloudWatch* for monitoring AWS resources; *Elastic Beanstalk* to deploy and execute custom applications written in Java, PHP and other languages; *Identity and Access Management* to securely control access to AWS services and resources.
- Content delivery: *Amazon CloudFront* makes easy to distribute content via a global network of edge locations.
- App services: *Simple Notification Service* to notify users; *Simple Queue Service* that implements a message queue; *Simple Workflow Service* to implement workflow-based applications.

Even though Amazon is best known to be the first IaaS provider (based on its EC2 and S3 services), it is now also a PaaS and SaaS provider, with services like *Elastic Beanstalk*, which allows users to quickly create, deploy, and manage applications using a large set of AWS services, *Amazon Machine Learning*, which provides visualization tools and wizards for easily creating machine learning models, and *Simple Email Service* providing a basic email-sending service.

Fig. 1 Amazon Web Services.

Fig. 2 Google Cloud Platform.

Google Cloud Platform

Google Cloud Platform is a set of cloud computing services provided by Google. The platform allows developers to define a wide range of web applications, from simple websites to scalable multitenancy applications. The services created by users run in the same supporting infrastructure that Google uses internally to run Google Search, YouTube, Maps, and Gmail. Google provides SDKs to define applications using several languages, libraries, and frameworks (e.g., GO, PHP, Java, Python and .Net).

The platform provides several services to build and scale an application (see Fig. 2):

- **Compute:** *Compute Engine*, an IaaS that allows developers to run virtual machine (VM) instances; *App Engine*, a PaaS that allows developers to create and host web applications in Google-managed data centers; *Container Engine*, a management and orchestration system for software container.
- **Storage and Databases:** *Cloud Storage*, a cloud storage web service for storing and accessing large and/or unstructured data sets; *Cloud Datastore*, a highly scalable NoSQL database service; *Cloud Bigtable*, a highly scalable NoSQL database service used by Google to power many core services, including Search, Analytics, Maps, and Gmail.

- Networking: *Cloud Virtual Network*, a managed networking functionality for web applications; *Cloud Load Balancing*, a load-balancer for compute resources in single or multiple regions.
- Big Data: *BigQuery*, a data warehouse enabling fast SQL queries; *Cloud Dataflow*, a data processing service for stream and batch execution of pipelines; *Cloud Pub/Sub*, a real-time messaging service to send and receive messages between applications.
- Machine Learning: *Cloud Machine Learning Engine*, a scalable machine learning service to train models and predict new data; *Cloud Natural Language API*, for extracting information mentioned in text documents, news articles or blog posts.
- Management Tools: *Stackdriver Monitoring*, to monitor cloud resources performance; *Stackdriver Logging*, for storing, monitoring, and alerting log data and events from google services.
- Identity and Security: *Cloud Identity & Access Management*, a service to establish a policy of access to the various services; *Cloud Key Management Service*, a key management for managing encryption of cloud services.

Microsoft Azure

Azure is an environment and a set of cloud services that can be used to develop cloud-oriented applications, or to enhance existing applications with cloud-based capabilities. The platform provides on-demand compute and storage resources exploiting the computational and storage power of the Microsoft data centers. Azure is designed for supporting high availability and dynamic scaling services that match user needs with a pay-per-use pricing model. The Azure platform can be used to perform the storage of large datasets, execute large volumes of batch computations, and develop SaaS applications targeted towards end-users.

Microsoft Azure includes three basic components/services as shown in Fig. 3:

- *Compute* is the computational environment to execute cloud applications. Each application is structured into roles: *Web role*, for Web-based applications; *Worker role*, for batch applications; *VM role*, for virtual-machine images.
- *Storage* provides scalable storage to manage: binary and text data (*Blobs*), non-relational tables (*Tables*), queues for asynchronous communication between components (*Queues*), and virtual disks (*Disks*).
- *Fabric controller* whose aim is to build a network of interconnected nodes from the physical machines of a single data center. The Compute and Storage services are built on top of this component.

Microsoft Azure provides also a set of services that can be used in many fields, like *Machine Learning*, to build cloud-based machine learning applications, or *IOT Hub*, to connect, monitor, and control IoT devices. Azure provides standard interfaces that allow developers to interact with its services. Moreover, developers can use IDEs like Microsoft Visual Studio and Eclipse to easily design and publish Azure applications.

Fig. 3 Microsoft Azure.

Fig. 4 IBM Bluemix.

IBM Bluemix

IBM Bluemix delivers services that can easily integrate with cloud applications without users needing to know how to install or configure them. It supports several programming languages and services for building, running and managing applications on the cloud (e.g., NET, Java, Node.js, PHP, Python, Ruby, Go).

With Bluemix customers can access three types of cloud computing platforms:

- *Bluemix public*, which provides all the necessary resources for an application development available to the general public;
- *Bluemix dedicated*, which provides a own Bluemix private environment that is hosted in an isolated container managed by Bluemix;
- *Bluemix Hybrid*, which allows customers to connect their dedicated services to the Public Bluemix services by maintaining data and sensitive services on premise.

IBM Bluemix offers mainly two compute services for defining applications: *Containers* and *OpenStack VMs*. *IBM Containers* permits developers to deploy, manage and run application on IBM platform by leveraging open-source Docker container technology (Merkel, 2014). Docker is an open platform used for building, shipping and running applications. *OpenStack Virtual Machines* allows running specific operating systems that users can customize.

The IBM Bluemix platform provides several services to build and scale an application (see Fig. 4):

- *Compute*: *Virtual servers* to deploy and scale virtual machines on demand; *GPU Servers* to deploy high-performance GPU servers; *Containers*, to deploy, manage and run application on IBM platform by leveraging open-source Docker container technology.
- *Storage*: *Object Storage*, to access unstructured data via with RESTful APIs; *File Storage*, a full-featured file storage; *Block Storage*, a scalable block storage services.
- *Network*: *Load Balancing*, a load-balancer for compute resources; *Direct Link*, to transfer data between a private infrastructure and IBM Bluemix services.
- *Mobile*: *Swift*, to write Swift mobile applications; *Mobile Foundation*, a set of APIs to manage the app life cycle.
- *Analytics*: *Analytics Services*, to extract insight from data; *Natural Language Understanding*, to extract meta-data from text such as sentiment, and relations.
- *Internet of Things*: *IOT platform*, which allows to communicate with and consume data from IOT devices.
- *Security*: *Firewalls* for protecting from malicious activities; *Security Software*, an intrusion protection system for the network and server/host level.

OpenStack

OpenStack is a cloud system that allows the management of large pools of processing, storage, and networking resources in a data center through a Web-based interface (Wen et al., 2012). The system has been designed, developed and released following four open principles:

- *Open source*: OpenStack is released under the terms of the Apache License 2.0;

Fig. 5 OpenStack.

Fig. 6 OpenNebula.

- *Open design*: Every six months there is a design summit to gather requirements and define new specifications for the upcoming release;
- *Open development*: A publicly available source code repository is maintained for the entire development process;
- *Open Community*: Most decisions are made by the OpenStack community using a lazy consensus model.

The modular architecture of OpenStack is composed by four main components, as shown in Fig. 5.

OpenStack *Compute* provides virtual servers upon demand by managing the pool of processing resources available in the data center. It supports different virtualization technologies (e.g., VMware, KVM) and is designed to scale horizontally. OpenStack *Storage* provides a scalable and redundant storage system. It supports Object Storage and Block Storage: the former allows storing and retrieving objects and files in the data center; the latter allows creating, attaching and detaching of block devices to servers. OpenStack *Networking* manages the networks and IP addresses. Finally, OpenStack *Shared Services* are additional services provided to ease the use of the data center. For instance, Identity Service maps users and services, Image Service manages server images, Database Service provides a relational database.

OpenNebula

OpenNebula (Sotomayor et al., 2009) is an open-source framework mainly used to build private and hybrid clouds. The main component of the OpenNebula architecture (see Fig. 6) is the *Core*, which creates and controls virtual machines by interconnecting them with a virtual network environment. Moreover, the Core interacts with specific storage, network and virtualization operations through pluggable components called *Drivers*. In this way, OpenNebula is independent from the underlying infrastructure and offers a uniform management environment.

Fig. 7 Eucalyptus.

The Core also supports the deployment of *Services*, which are a set of linked components (e.g., Web server, database) executed on several virtual machines. Another component is the *Scheduler*, which is responsible for allocating the virtual machines on the physical servers. To this end, the Scheduler interacts with the Core component through appropriate deployment commands.

OpenNebula can implement a hybrid cloud using specific Cloud Drivers that allow interacting with external clouds. In this way, the local infrastructure can be supplemented with computing and storage resources from public clouds. Currently, OpenNebula includes drivers for using resources from Amazon EC2 and Eucalyptus.

Eucalyptus

Eucalyptus (Elastic Utility Computing Architecture for Linking Your Programs To Useful Systems) is an open source and paid software platform for implementing IaaS in a private or hybrid cloud computing environment (Endo *et al.*, 2010). Eucalyptus enables developers to use compute, storage, and network resources that can be dynamically scaled and can be used to build web-based applications. Companies can use AWS-compatible services, images, and scripts on their own on-premises IaaS environments, without using a public Cloud environment like AWS. It is simple to interact with Eucalyptus since it provides a console to self-service provision and configure compute, network, and storage resources.

Eucalyptus is based on five basic components as shown in Fig. 7. The *Node Controller* (NC) hosts the virtual machine instances and manages the virtual network endpoints. The *Cluster Controller* (CC) acts as the front end for a cluster and it is responsible for deploying and managing instances on NCs. The *Storage Controller* (SC) provides persistent block storage and allows the creation of snapshots of volumes. The *Cloud Controller* (CLC) is the front-end for managing cloud services and performs high-level resource scheduling and system accounting. CLC also allows interacting with the components of the Eucalyptus infrastructure providing an AWS-compatible web services interface to customers. *Walrus Storage Controller* (WS3) offers a persistent storage to all of the virtual machines in the Eucalyptus cloud and can be used to store machine images and snapshots. WS3 can be used with AWS S3 APIs.

Closing Remarks

This article described the main services provided by the most popular cloud infrastructures currently in use. The systems presented in this article were either public clouds Amazon Web Services (AWS), Google Cloud Platform, Microsoft Azure and IBM Bluemix or private clouds OpenStack, OpenNebula and Eucalyptus. As discussed above, the public cloud systems provide a variety of services that implement all the three main cloud service models, i.e., Infrastructure as a Service (IaaS), Platform as a Service (PaaS) and Software as a Service (SaaS). On the other hand, the private cloud systems are more focused on the IaaS model, as they provide services for the management of large pools of processing, storage, and networking resources in a data center, by exploiting a variety of virtualization techniques.

Infrastructures for High-Performance Computing: Cloud Computing Development Environments

Fabrizio Marozzo and Paolo Trunfio, University of Calabria, Rende, Italy

© 2019 Elsevier Inc. All rights reserved.

Introduction

Developing cloud applications may be a complex task, with specific issues that go beyond those of stand-alone application programming. For instance, cloud programming must deal with deployment, scalability and monitoring aspects that are not easy to handle without the use of ad-hoc environments (Talía *et al.*, 2015). In fact, to simplify the development of cloud applications, cloud computing development environments are often used. This article describes some of the most representative cloud computing development environments currently in use. The environment presented in this paper are classified into four types:

- *Integrated development environments*, which are used to code, debug, deploy and monitor cloud applications that are executed on a cloud infrastructure. The environments discussed in this article are *Eclipse*, *Visual Studio* and *IntelliJ*.
- *Parallel-processing development environments*, which are used to define parallel applications for processing large amount of data that are run on a cluster of virtual machines provided by a cloud infrastructure. The environments presented here are *Hadoop* and *Spark*.
- *Workflow development environments*, which are used to define workflow-based applications that are executed on a cloud infrastructure. The examples discussed here are *Swift* and *DMCF*.
- *Data-analytics development environments*, which are used to define data analysis applications through machine learning and data mining tools provided by a cloud infrastructure. The examples presented in this article are *Azure ML* and *BigML*.

Integrated Development Environments

Eclipse

Eclipse (see Section Relevant Websites) is one of the most popular integrated development environments (IDEs) for software programmers that can be used to define applications in C++ , Java, JavaScript, PHP, Python, R and so on, which can be run and deployed on multiple operating systems and computing platforms, including the most popular cloud computing infrastructures.

The Eclipse platform can be extended by installing plug-ins, such as development toolkits for novel programming languages and/or systems. Plug-ins can be programmed using Eclipse APIs and can be run on any of the supported operating systems. At the core of Eclipse is an architecture for discovering, loading, and running plug-ins. In addition to providing a development environment for programming languages, Eclipse supports development for most popular application servers (e.g., Tomcat, GlassFish) and is often capable of installing the required server directly from the IDE. It supports remote debugging that allows programmers to debug the code of applications running on servers.

Eclipse provides three types of products:

- *Desktop IDE*, for defining and running Java applications, C/C++ software, PHP web pages and so on in a desktop PC;
- *Cloud IDEs*, a Cloud IDE to develop software using a browser;
- *IDE Platforms*, a set of frameworks and common services to support the use of Eclipse as a component model.

Eclipse allows to program cloud applications for the main public and private cloud infrastructures. For example, *AWS Toolkit for Eclipse* is an open source plug-in that allows developers to define, debug, and deploy Java applications on Amazon Web Services. *IBM Eclipse Tools for Bluemix* enables the deployment and integration of many services from Bluemix into applications. Finally, *Google Plugin for Eclipse* simplifies the development of web applications that utilize Google cloud technology.

Visual Studio

Microsoft Visual Studio (see Section Relevant Websites) is a Microsoft IDE that allows users to develop, test, and deploy applications for the web, desktop, cloud, mobile, and game consoles. It is fully integrated with Microsoft technologies such as Windows API, Microsoft Office, Microsoft Azure and Windows Store.

Visual Studio includes a code editor for supporting code completion and refactoring. An integrated debugger helps to observe the run-time behaviour of programs and find problems. The functionality of the IDE can be enhanced through plug-ins, such as visual tools aiding in the development of GUI of web, desktop and mobile applications.

Visual Studio supports the most popular programming languages. For example, C++ for performance across a wide range of devices; Python for cross-platform scripting; R, for data processing; Node.js for scalable applications in JavaScript; C# as a multi-paradigm programming language for a variety of platforms, including the cloud.

Visual Studio allows to program cloud applications for Microsoft Azure and other cloud infrastructures. For example, *Visual Studio Tools for Azure* allows building, managing, and deploying cloud applications on Azure, whilst the *AWS Toolkit for Visual Studio* is a plugin that permits to develop, debug, and deploy .NET applications that use Amazon Web Services.

IntelliJ

IntelliJ (see Section Relevant Websites) is an IDE for web, mobile, cloud and enterprise development that supports languages like Java, JavaScript, Groovy and Scala. It is developed by the JetBrains company and is available in an Apache Licensed community edition, and in a commercial edition. The community edition allows Java and Android development. The commercial edition extends the community edition with support for web and enterprise development. Both community and commercial editions support cloud development with sponsorship of the main cloud providers.

One important feature of IntelliJ is code completion made by analyzing the source code of a user. Specifically, IntelliJ indexes user source code, for providing relevant code suggestions and on-the-fly code analysis. As the previous two systems discussed above, IntelliJ supports plugins for adding additional functionality to the IDE, such as version control systems (e.g., GIT), databases (e.g., Microsoft SQL Server) and automatic task runners (e.g., Grunt).

IntelliJ IDEA supports the most popular Java application servers, such as Tomcat, JBoss and Glassfish. A developer can deploy, debug and monitor an application onto an application server. Moreover, IntelliJ IDEA provides dedicated plug-ins that allows programmers to manage Docker virtual machines.

IntelliJ allows developers to create and interact with cloud applications using the API of the most popular cloud infrastructures. For example, through *AWS Manager Plugin* it provides integration with AWS services like EC2, RDS and S3, whilst *Cloud Tools for IntelliJ* is a Google-sponsored plugin that allows IntelliJ developers to interact with Google Cloud Platform services.

Parallel-Processing Development Environments

Hadoop

Apache Hadoop (see Section Relevant Websites) is commonly used to develop parallel applications that analyse big amounts of data. It can be adopted for developing parallel applications using many programming languages (e.g., Java, Ruby, Python, C++) based on the MapReduce programming model (Dean and Ghemawat, 2004) on a cluster or on a cloud platform. Hadoop relieves developers from having to deal with classical distributed computing issues, such as load balancing, fault tolerance, data locality, and network bandwidth saving. The Hadoop project is not only about the MapReduce programming model (Hadoop MapReduce module), as it includes other modules such as:

- *Hadoop Distributed File System (HDFS)*: a distributed file system providing fault tolerance with automatic recovery, portability across heterogeneous commodity hardware and operating systems, high-throughput access and data reliability.
- *Hadoop YARN*: a framework for cluster resource management and job scheduling.
- *Hadoop Common*: common utilities that support the other Hadoop modules.

With the introduction of YARN in 2013, Hadoop turns from a batch processing solution into a platform for running a large variety of data applications, such as streaming, in-memory, and graphs analysis. As a result, Hadoop became a reference for several other frameworks, such as: Giraph (see Section Relevant Websites) for graph analysis; Storm (see Section Relevant Websites) for streaming data analysis; Hive (see Section Relevant Websites), which is a data warehouse software for querying and managing large datasets; Pig (see Section Relevant Websites), which is as a dataflow language for exploring large datasets; Tez (see Section Relevant Websites) for executing complex directed-acyclic graph of data processing tasks; Oozie (see Section Relevant Websites), which is a workflow scheduler system for managing Hadoop jobs.

Hadoop is available in most cloud infrastructures. For example, the *HDInsight* service by Microsoft Azure, the *Amazon Elastic MapReduce (EMR)* service by AWS, and Google Cloud Dataproc service by Google Cloud.

Spark

Apache Spark (see Section Relevant Websites) is an open-source framework for in-memory data analysis and machine learning developed at UC Berkeley in 2009. It can process distributed data from several sources, such as HDFS, HBase, Cassandra, and Hive. It has been designed to efficiently perform both batch processing applications (similar to MapReduce) and dynamic applications like streaming, interactive queries, and graph analysis. Spark is compatible with Hadoop data and it can run in Hadoop clusters through the YARN module. However, in contrast to Hadoop's two-stage MapReduce paradigm in which intermediate data are always stored in distributed file systems, Spark stores data in a cluster's memory and queries it repeatedly so as to obtain better performance for several classes of applications (e.g., interactive jobs, real-time queries, and stream data) (Xin et al., 2013). The Spark project has different components:

- Spark Core contains the basic functionalities of the library such as for manipulating collections of data, memory management, interaction with distributed file systems, task scheduling, and fault recovery.

- Spark SQL provides API to query and manipulate structured data using standard SQL or Apache Hive variant of SQL.
- Spark Streaming provides an API for manipulating streams of data.
- GraphX is a library for manipulating and analyzing big graphs.
- MLlib is a scalable machine learning library on top of Spark that implements many common machine learning and statistical algorithms.

Several big companies and organizations use Spark for big data analysis purpose: for example, Ebay uses Spark for log transaction aggregation and analytics, Kelkoo for product recommendations, SK Telecom analyses mobile usage patterns of customers.

Similarly to Hadoop, most cloud infrastructures provide Spark as a service, like *IBM Analytics for Apache Spark*, *Azure HDInsight* and *Google Cloud Dataproc*.

Workflow Development Environments

Swift

Swift (Wilde *et al.*, 2011) is a implicitly parallel scripting language that runs workflows across several distributed systems, like supercomputers, clusters, grids and clouds. The Swift language has been designed at the University of Chicago and at the Argonne National Lab to provide users with a workflow-based language for cloud computing.

Swift separates the application workflow logic from runtime configuration. This approach allows a flexible development model. The Swift language allows invocation and running of external application code and allows binding with application execution environments without extra coding from the user. Swift/K is the previous version of the Swift language that runs on the Karajan grid workflow engine across wide area resources. Swift/T is a new implementation of the Swift language for high-performance computing. In this implementation, a Swift program is translated into an MPI program that uses the Turbine and ADLB runtime libraries for scalable dataflow processing over MPI. The Swift-Turbine Compiler (STC) is an optimizing compiler for Swift/T and the Swift Turbine runtime is a distributed engine that maps the load of Swift workflow tasks across multiple computing nodes. Users can also use Galaxy (Giardine *et al.*, 2005) to provide a visual interface for Swift.

The Swift language provides a functional programming paradigm where workflows are designed as a set of code invocations with their associated command-line arguments and input and output files. Swift is based on a C-like syntax and uses an implicit data-driven task parallelism (Justin *et al.*, 2014). In fact, it looks like a sequential language, but being a dataflow language, all variables are futures, thus execution is based on data availability. When input data is ready, functions are executed in parallel. Moreover, parallelism can be exploited through the use of the *for each* statement. The Turbine runtime comprises a set of services that implement the parallel execution of Swift scripts exploiting the maximal concurrency permitted by data dependencies within a script and by external resource availability. Swift has been used for developing several scientific data analysis applications, such as prediction of protein structures, modeling the molecular structure of new materials, and decision making in climate and energy policy.

Data Mining Cloud Framework

The Data Mining Cloud Framework (DMCF) is a software system developed at the University of Calabria for designing and executing data analysis workflows on clouds (Belcastro *et al.*, 2015). A Web-based user interface allows users to compose their applications and submit them for execution over cloud resources, according to a Software-as-a-Service (SaaS) approach.

The DMCF architecture has been designed to be deployed on different cloud settings. Currently, there are two different deployments of DMCF: (1) on top of a Platform-as-a-Service (PaaS) cloud, i.e., using storage, compute, and network APIs that hide the underlying infrastructure layer; (2) on top of an Infrastructure-as-a-Service (IaaS) cloud, i.e., using virtual machine images (VMs) that are deployed on the infrastructure layer.

The DMCF software modules can be grouped into *web components* and *compute components*. DMCF allows users to compose, check, and run data analysis workflows through a HTML5 web editor. The workflows can be defined using two languages: Visual Language for Cloud (VL4Cloud) (Marozzo *et al.*, 2016) and JavaScript for Cloud (JS4Cloud) (Marozzo *et al.*, 2015). Both languages use three key abstractions:

- *Data* elements, representing input files (e.g., a dataset to be analyzed) or output files (e.g., a data mining model).
- *Tool* elements, representing software tools used to perform operations on data elements (partitioning, filtering, mining, etc.).
- *Tasks*, which represent the execution of Tool elements on given input Data elements to produce some output Data elements.

The DMCF editor generates a JSON descriptor of the workflow, specifying what are the tasks to be executed and the dependency relationships among them. The JSON workflow descriptor is managed by the DMCF workflow engine that is in charge of executing workflow tasks on a set of workers (virtual processing nodes) provided by the cloud infrastructure. The workflow engine implements a data-drive task parallelism that assigns workflow tasks to idle workers as soon as they are ready to execute.

Data-Analytics Development Environments

Microsoft Azure Machine Learning

Microsoft Azure Machine Learning (Azure ML, see Section Relevant Websites) is a SaaS that provides a Web-based machine learning environment for the creation and automation of machine learning workflows. Through its user-friendly interface, data scientists and developers can perform several common data analysis/mining tasks on their data and automate their workflows.

Using its drag-and-drop interface, users can import their data in the environment or use special readers to retrieve data from several sources, such as Web URL (HTTP), OData Web service, Azure Blob Storage, Azure SQL Database, Azure Table. After that, users can compose their data analysis workflows where each data processing task is represented as a block that can be connected with each other through direct edges, establishing specific dependency relationships among them. Azure ML includes a rich catalog of processing tool that can be easily included in a workflow to prepare/transform data or to mine data through supervised learning (regression or classification) or unsupervised learning (clustering) algorithms. Optionally, users can include their own custom scripts (e.g., in R or Python) to extend the tools catalog. When workflows are correctly defined, users can evaluate them using some testing dataset. Users can easily visualize the results of the tests and find very useful information about models accuracy, precision and recall. Finally, in order to use their models to predict new data or perform real time predictions, users can expose them as Web services. Always through a Web-based interface, users can monitor the Web services load and use by time.

Azure Machine Learning is a fully managed service provided by Microsoft on its Azure platform; users do not need to buy any hardware/software nor manage virtual machine manually. One of the main advantage of working with Azure Machine Learning is its auto-scaling feature: models are deployed as elastic Web services so as users do not have to worry about scaling them if the models usage increased.

BigML

BigML (see Section Relevant Websites) is provided as a Software-as-a-Service (SaaS) for discovering predictive models from data sources and using data classification and regression algorithms. The distinctive feature of BigML is that predictive models are presented to users as interactive decision trees. The decision trees can be dynamically visualized and explored within the BigML interface, downloaded for local usage and/or integration with applications, services, and other data analysis tools. Extracting and using predictive models in BigML consists in multiple steps, as detailed in the following:

- *Data source setting and dataset creation.* A data source is the raw data from which a user wants to extract a predictive model. Each data source instance is described by a set of columns, each one representing an instance feature, or field. One of the fields is considered as the feature to be predicted. A dataset is created as a structured version of a data source in which each field has been processed and serialized according to its type (numeric, categorical, etc.).
- *Model extraction and visualization.* Given a dataset, the system generates the number of predictive models specified by the user, who can also choose the level of parallelism level for the task. The interface provides a visual tree representation of each predictive model, allowing users to adjust the support and confidence values and to observe in real time how these values influence the model.
- *Prediction making.* A model can be used individually, or in a group (the so-called ensemble, composed of multiple models extracted from different parts of a dataset), to make predictions on new data. The system provides interactive forms to submit a predictive query for a new data using the input fields from a model or ensemble. The system provides APIs to automate the generation of predictions, which is particularly useful when the number of input fields is high.
- *Models evaluation.* BigML provides functionalities to evaluate the goodness of the predictive models extracted. This is done by generating performance measures that can be applied to the kind of extracted model (classification or regression).

Closing Remarks

This article described four categories of cloud computing development environments. *Integrated development environments* are used to code, debug, deploy and monitor cloud applications that are executed on a cloud infrastructure. *Parallel-processing development environments* are used to define parallel applications for processing large amount of data that are run on a cluster of virtual machines provided by a cloud infrastructure. *Workflow development environments* are used to define workflow-based applications that are executed on a cloud infrastructure. *Data-analytics development environments* are used to define data analysis applications through machine learning and data mining tools provided by a cloud infrastructure. For each category, the article described some of the most representative cloud computing development environments currently in use, including their main features, provided services and available implementations.

Cloud-Based Bioinformatics Tools

Barbara Calabrese, University “Magna Graecia”, Catanzaro, Italy

Introduction

The availability of high-throughput technologies, such as mass spectrometry, microarray, and next generation sequencing, and the application of genomics and pharmacogenomics studies of large populations, are producing an increasing amount of experimental and clinical data, as well as specialized databases spread over the Internet (Calabrese and Cannataro, 2015a,b). The availability of huge volumes of omics data poses new problems in the storage, preprocessing and analysis of data. Main challenges regard: (i) The efficient storage, retrieval and integration of experimental data; (ii) their efficient and high-throughput preprocessing and analysis; (iii) the building of reproducible “in silico” experiments; (iv) the annotation of omics data with pre-existing knowledge stored into ontologies (e.g., Gene Ontology) or specialized databases; (v) the integration of omics and clinical data.

Traditionally, the management and analysis of omics data was performed through the use of bioinformatics tools, often implemented as web services, whereas data were stored in geographically distributed biological databases. This computing and storage model do not allow to manage high volume data and therefore it is needed to adopt new computing models (Agapito *et al.*, 2017).

Cloud computing may play an important role in many phases of the bioinformatics analysis pipeline, from data management and processing, to data integration and analysis, including data exploration and visualization (Calabrese and Cannataro, 2015b; Dudley *et al.*, 2010). Currently, high performance computing is used to face the large processing power required when processing omics data, while web services and workflows are used to face the complexity of the bioinformatics pipeline that comprises several steps. Cloud computing may be the glue that put together those mainstreams technologies already used in bioinformatics (parallelism, service orientations, knowledge management), with the elasticity and ubiquity made available by the cloud (Schadt, 2011).

Moreover, by entering the data and software in the cloud and providing them as a service, it is possible to get a level of integration that improves the analysis and the storage of bioinformatics big-data. In particular, as a result of this unprecedented growth of data, the provision of data as a service (Data as a Service, DaaS) is of extreme importance. DaaS provides data storage in a dynamic virtual space hosted by the cloud and allows to have updated data that are accessible from a wide range of connected devices on the web. An example is represented by the DaaS of Amazon Web Services (AWS, see “Relevant Websites section”), which provides a centralized repository of public data sets (Fusaro *et al.*, 2011).

Despite the many benefits associated with cloud computing, it currently presents some issues and open problems such as privacy and security, geographical localization of data, legal responsibilities in the case of data leaks, that are particularly important when managing sensitive data such as the patients data stored and processed in genomics and pharmacogenomics studies, and more in general when clinical data are transferred to the cloud.

Cloud-Based Bioinformatics Tools

In recent years, there have been several efforts to develop cloud-based tools to execute different bioinformatics tasks (Dai *et al.*, 2012), e.g., read mapping applications, sequences alignment, gene expression analysis (Henry *et al.*, 2014). Some examples of academic and commercial SaaS (Software as a Service) bioinformatics tools are reported in the following section.

CloudBurst (Schatz, 2009) and *CloudAligner* (Nguyen *et al.*, 2011) are parallel read-mapping algorithms optimized for mapping next-generation sequence (NGS) data to the human genome and other reference genomes, for use in a variety of biological analyses including SNP discovery, genotyping and personal genomics. They use the open-source Hadoop implementation of MapReduce to parallelize execution using multiple compute nodes. Specifically, CloudAligner has been designed for more long sequences.

Balaur (Popic and Batzoglu, 2017) is a recent privacy preserving read mapping technique for hybrid clouds that securely outsources a significant portion of the read-mapping task to the public cloud, while being highly competitive with existing state-of-the-art aligners in speed and accuracy. At a high level, BALAUR can be summarized in the following two phases: (1) Fast identification of a few candidate alignment positions in the genome using the locality sensitive hashing (LSH) (on the secure private client) and (2) evaluation of each candidate using secure kmer voting (on the untrusted public server). The proposed approach can easily handle typical genome-scale datasets and is highly competitive with non-cryptographic state-of-the-art read aligners in both accuracy and runtime performance on simulated and real read data.

GENESIS (Gonzalez *et al.*, 2015) provides a cloud-based system that allows users to directly process and analyze next-generation sequencing (NGS) data through a user-friendly graphical user interface (GUI). The first objectives of the GENESIS (formerly GEM.app) platform are: (1) To assist scientists/clinicians in transferring and processing genomic data, (2) to produce accurate, high quality, and reproducible results, (3) to provide a highly available and scalable analytical framework for analyzing variant data, and (4) to provide tools for user-driven data-sharing and collaboration. Hereby, GENESIS enables users of varying

computational experience to iteratively test many different filtering strategies in a matter of seconds and to browse very large sets of full exomes and genomes in real-time.

DNANexus (see “Relevant Websites section”) allows next-generation sequence (NGS) analysis and visualization. It uses cloud computing from Amazon Web Services. Customers of DNANexus use those computational resources to run analysis programs on DNA sequence data and to store that data. The product includes applications for read mapping, RNA-seq, ChIP-seq, and genomic variant analysis.

Tute Genomics is a cloud-based clinical genome interpretation platform that enables researchers and clinicians to utilize human genome data for scientific discovery and individualized treatment. Tute Genomics has developed the most advanced analytical methods for genome analysis by incorporating proprietary machine-learning algorithms into a cloud based application that allows researchers to analyze and interpret entire human genomes and discover genes and biomarkers at an unprecedented rate.

TGex (see “Relevant Websites section”) provides rapid and accurate identification of causal mutations in rare diseases. TGex is a knowledge-driven Next Generation Sequencing (NGS) cloud-based analysis and interpretation solution based on the GeneCards Suite Knowledgebase. It uses VarElect, the NGS PhenoTyper, to score and prioritize variant-genes based on disease/phenotype of interest. TGex provides analysts with all the tools required for filtering and ranking variants, together with the ability to quickly assess evidence for the association between candidate genes and relevant phenotypes, all in one easy-to-use, consolidated view.

BaseSpace (see “Relevant Websites section”) offers a wide variety of NGS (next-generation sequencing) data analysis applications that are developed or optimized by Illumina, or from a growing ecosystem of third-party app providers. BaseSpace is a cloud platform to be directly integrated in to the industry’s leading sequencing platforms, with no cumbersome and time consuming data transfer steps.

CloudRS (Chen *et al.*, 2013) corrects sequencing errors in next-generation sequencing (NGS) data. CloudRS is a MapReduce application, based on the multiple sequence alignment (MSA) approach, that emulates the concept of the error correction algorithm of ALLPATHS-LG on the MapReduce framework. The software applies a two-stage majority voting mechanism for correcting errors in each ReadStack. It contains several modules with at least one mapper and/or reducer task.

Another Hadoop-based tool is *Crossbow* (Langmead *et al.*, 2009) that combines the speed of the short read aligner Bowtie with the accuracy of the SNP caller SOAPsnp to perform alignment and SNP detection for multiple whole-human datasets per day.

VAT (Variant Annotation Tool) (Habegger *et al.*, 2012) has been developed to functionally annotate variants from multiple personal genomes at the transcript level as well as to obtain summary statistics across genes and individuals. VAT also allows visualization of the effects of different variants, integrates allele frequencies and genotype data from the underlying individuals and facilitates comparative analysis between different groups of individuals. VAT can either be run through a command-line interface or as a web application. Finally, in order to enable on-demand access and to minimize unnecessary transfers of large data files, VAT can be run as a virtual machine in a cloud-computing environment.

Another cloud-computing pipeline for calculating differential gene expression in large RNA-Seq datasets is *Myrna* (Langmead *et al.*, 2010). Myrna integrates short read alignment with interval calculations, normalization, aggregation and statistical modeling in a single computational pipeline. After alignment, Myrna calculates coverage for exons, genes, or coding regions and differential expression using either parametric or non-parametric permutation tests. Myrna exploits the availability of multiple computers and processors where possible and can be run on the cloud using Amazon Elastic MapReduce, on any Hadoop cluster, or on a single computer (bypassing Hadoop entirely).

PeakRanger (Feng *et al.*, 2011) is a software package for the analysis in Chromatin Immuno-Precipitation Sequencing (ChIP-seq) technique. This technique is related to NGS and allows investigating the interactions between proteins and DNA. Specifically, PeakRanger is a peak caller software package that can be run in a parallel cloud computing environment to obtain extremely high performance on very large data sets.

For spectrometry-based proteomics research, *ProteoCloud* (Muth *et al.*, 2013) is a freely available, full-featured cloud-based platform to perform computationally intensive, exhaustive searches using five different peptide identification algorithms. ProteoCloud is entirely open source, and is built around an easy to use and cross-platform software client with a rich graphical user interface. This client allows full control of the number of cloud instances to initiate and of the spectra to assign for identification. It also enables the user to track progress, and to visualize and interpret the results in detail.

An environment for the integrated analysis of microRNA and mRNA expression data is provided by *BioVLAB-MMIA* (Lee *et al.*, 2012). Recently, a new version called BioVLAB-NGS, deployed on both Amazon cloud and on a high performance, public available server called MAHA, has been developed (Chae *et al.*, 2014). By utilizing next generation sequencing (NGS) data and integrating various bioinformatics tools and databases, BioVLAB-MMIA-NGS offers several advantages, such as a more accurate data sequencing for determining miRNA expression levels or the implementation of various computational methods for characterizing miRNAs.

Cloud4SNP (Agapito *et al.*, 2013) is a Cloud-based bioinformatics tool for the parallel pre-processing and statistical analysis of pharmacogenomics SNP microarray data. Cloud4SNP is able to perform statistical tests in parallel, by partitioning the input data set and using the virtual servers made available by the Cloud. Moreover, different statistical corrections such as Bonferroni, False Discovery Rate, or none correction, can be applied in parallel on the Cloud, allowing the user to choose among different statistical models, implementing a sort of parameter sweep.

AGX (see “Relevant Websites section”) is a cloud-based service that can analyze single vcf sample, compare tumour/normal samples and perform trio analysis. This online system permits to upload, access and analyze data anywhere with Internet connection. User could employ standard inheritance models like Autosomal dominant or improve it by checking quality of the genotype calls in trio samples.

Nephele (see “Relevant Websites section”) is a project from the National Institutes of Health (NIH) that brings together microbiome data and analysis tools in a cloud computing environment. *Nephele*’s advanced analysis pipelines include multiple stages of data processing, many of which can be configured by modifying parameters provided in the submission form.

Vivar (Sante *et al.*, 2014) represents a comprehensive analysis platform for the processing, analysis and visualization of structural variation based on sequencing data or genomic microarrays, enabling the rapid identification of disease loci or genes. *Vivar* allows user to scale analysis spreading the work load over multiple (cloud) servers, it has user access control to keep data safe but it is still easy to share, and it is easy expandable as analysis techniques advance.

GenomeVIP (Mashl *et al.*, 2017) performs variant discovery on Amazon’s Web Service (AWS) cloud or on local high-performance computing clusters. It provides a collection of analysis tools and computational frameworks for streamlined discovery and interpretation of genetic variants. The server and runtime environments can be customized, updated, or extended.

MyVariant.info uses a generalizable cloud-based model for organizing and querying biological annotation information. It utilizes the nomenclature from the Human Genome Variation Society (HGVS) to define its primary keys. The tool contains more than 500 variant-specific annotation types from dozens of resources, covering more than 334 million unique variants, including both coding and non-coding variants.

PorthoMCL (Tabari and Su, 2017) facilitates comparative genomics analysis through exploiting the exponentially increasing number of sequenced genomes. *PorthoMCL* is a parallel orthology prediction tool using the Markov Clustering algorithm (MCL). This application was developed to identify orthologs and paralogs in any number of genomes. It can be run on a wide range of high performance computing clusters and cloud computing platforms.

Falco (Yang *et al.*, 2017) is a cloud-based framework designed for multi-sample analysis of transcriptomic data in an efficient and scalable manner. *Falco* utilizes state-of-the-art big data technology of Apache Hadoop and Apache Spark to perform massively parallel alignment, quality control, and feature quantification of single-cell transcriptomic data in Amazon Web Service (AWS) cloud-computing environment.

Open Challenges

Omics data extracted by patients’ samples, as in pharmacogenomics studies, as well as other clinical data and exams (e.g., bio-images and/or bio-signals), are sensitive data and pose specific constraints in terms of privacy and security. On the other hand, cloud computing presents open issues such as privacy and security, geographical localization of data, legal responsibilities in the case of data leaks.

In general, omics and clinical data managed through a cloud are susceptible to unauthorized access and attacks. Specifically, in Johnson (2009), the author puts in evidence that storing huge volumes of patients’ sensitive medical data in third-party cloud storage is susceptible to loss, leakage or theft. The privacy risk of cloud environment includes the failure of mechanisms for separating storage, memory, routing, and even reputation between different tenants of the shared infrastructure. The centralized storage and shared tenancy of physical storage space means the cloud users are at higher risk of disclosure of their sensitive data to unwanted parties.

Moreover, threats to the data privacy in the cloud include spoofing identity, tampering with the data, repudiation, and information disclosure. In spoofing identity attack, the attacker pretends to be a valid user whereas data tampering involves malicious alterations and modification of the content. Repudiation threats are concerned with the users who deny after performing an activity with the data. Information disclosure is the exposure of information to the entities having no right to access information. The same threats prevail for the health data stored and transmitted on the third-party cloud servers.

Thus, it is needed to adopt secure protection schemes and cryptographic techniques to defend the sensitive information of the medical and biological records. There is considerable work on protecting data from privacy and security attacks. The NIST has developed specific guidelines to help consumers to protect their data in the Cloud (Grance and Jansen, 2012).

In Abbas and Khan (2014), a detailed discussion relative to the security and privacy requirements for cloud-based applications is reported. Specifically, the main requirements can be summarized in the following way:

- *Integrity*: It is needed to guarantee that the health data collected by a system or provided to any entity is true representation of the intended information and has not been modified in any way.
- *Confidentiality*: The health data of patients must be kept completely undisclosed to the unauthorized entities.
- *Authenticity*: The entity requesting access is authentic. In the healthcare systems, the information provided by the healthcare providers and the identities of the entities accessing such information must be verified.
- *Accountability*: An obligation to be responsible in light of the agreed upon expectations. The patients or the entities nominated by the patients should monitor the use of their health information whenever that is accessed at hospitals, pharmacies, insurance companies etc.
- *Audit*: It is needed to ensure that all the healthcare data is secure and all the data access activities in the e-Health cloud are being monitored.
- *Non-Repudiation*: Repudiation threats are concerned with the users who deny after performing an activity with the data. For instance, in the healthcare scenario neither the patients nor the doctors can deny after misappropriating the health data.
- *Anonymity*: It refers to the state where a particular subject cannot be identified. For instance, identities of the patients can be made anonymous when they store their health data on the cloud so that the cloud servers could not learn about the identity.

- *Unlinkability*: It refers to the use of resources or items of interest multiple times by a user without other users or subjects being able to interlink the usage of these resources. More specifically, the information obtained from different flows of the health data should not be sufficient to establish linkability by the unauthorized entities.

Finally, in the cloud, physical storages could be widely distributed across multiple jurisdictions, each of which may have different laws regarding data security, privacy, usage, and intellectual property. Data in the cloud may have more than one legal location at the same time, with differing legal consequences.

In the last years, to investigate these issues and propose secure solutions for genomic data, the NIH-funded National Center for Biomedical Computing iDASH (integrating Data for Analysis, ‘anonymization’ and SHaring) hosted the second Critical Assessment of Data Privacy and Protection competition. The aim is to assess the capacity of cryptographic technologies for protecting computation over human genomes in the cloud (Tang *et al.*, 2016). Data scientists were challenged to design practical algorithms for secure outsourcing of genome computation tasks in working software, whereby analyses are performed only on encrypted data. They were also challenged to develop approaches to enable secure collaboration on data from genomic studies generated by multiple organizations. The results of the competition indicated that secure computation techniques can enable comparative analysis of human genomes, but greater efficiency (in terms of compute time and memory utilization) are needed before they are sufficiently practical for real world environment.

Closing Remarks

Applications and services in bioinformatics data analysis pose quite demanding requirements. The fulfillment of those requirements could result in the development of comprehensive bioinformatics data analysis pipeline easy to use, available through the Internet, that may increase the knowledge in biology and medicine.

Naturally, the adoption of this technology with its benefits will determine a reduction of costs and the possibility of also providing new powerful services. However, a number of open issues and problems, such as privacy and security, geographical localization of data, legal responsibilities in the case of data leaks, that are particularly important when managing patients’ data stored and processed in the cloud, need to be considered in the adoption of cloud-based bioinformatics solutions.

Cloud-Based Bioinformatics Platforms

Barbara Calabrese, University “Magna Graecia”, Catanzaro, Italy

© 2019 Elsevier Inc. All rights reserved.

Introduction

Research in life sciences are more and more based on the large datasets produced by high throughput platforms (e.g mass spectrometry, microarray, and next generation sequencing). The application of omics sciences, such as genomics, proteomics and interactomics, on large populations is producing an increasing amount of experimental data (“big data”), as well as specialized databases spread over the Internet ([Greene et al., 2014](#)).

However, the storage, preprocessing and analysis of this experimental data are becoming the main bottleneck of the bioinformatics analysis pipeline, by posing several issues. In fact, as the amount of digital information increases, the ability to manage this data becomes a growing problem. This data holds the keys to future clinical advances, but often remains inaccessible to researchers.

Cloud computing is a computing model that has spread very rapidly in recent years for the supply of IT resources of different nature, through services accessible via the network. Specifically, Cloud can provide Virtual Machines (VM) in the sense of hardware resources, platforms to deploy applications or ready-to-use services ([Mell and Grance, 2011](#)). This computing model guarantees new advantages related to massive and scalable computing resources available on demand, virtualization technology and payment for use as needed. Therefore, the role of cloud computing has become crucial in many steps of the bioinformatics analysis pipeline, from data management and processing, to data integration and analysis, including data exploration and visualization. Cloud Computing can be the enabling factor for data sharing and integration at a large scale. In the paper ([Merelli et al., 2014](#)), the authors discussed high performance computing (HPC) solutions in bioinformatics and Big Data analysis paradigms for computational biology. Specifically, the authors pointed out that cloud computing addresses big data storage and analysis issues in many fields of bioinformatics, thanks to the virtualization that avoid to move too big data.

Background/Fundamentals

A working definition of cloud computing comes from the work of [Mell and Grance \(2011\)](#) from the National Institute of Standards and Technology, United States Department of Commerce. Their definition focuses on computing resources which can be accessed from anywhere and may be provisioned online. It also specifies five characteristics of cloud computing, three service models and four deployment methods ([Calabrese and Cannataro, 2015a](#)). According to this definition, the five key characteristics of cloud services are:

- on demand self service: a consumer can acquire computing power unilaterally and automatically without requiring any human intervention by the service provider;
- broad network access: the computational capabilities are accessible on the Internet in accordance with standard mechanisms;
- resource pooling: users have the impression that the available resources are unlimited and can be purchased in any amount and at any time. Resources of the service provider come together to serve a variety of consumers, according to a multi-tenant model. The physical and virtual resources are dynamically assigned and reassigned to consumers, based on their requests without having any control or knowledge of the exact location of the resources assigned to him/her;
- rapid elasticity: resources are able to be quickly allocated and elastically;
- measured services: the cloud systems automatically control and optimize resource use by evaluating appropriate parameters (e.g. storage, processing power, bandwidth and active user accounts).

[Vaquero et al. \(2009\)](#) collected 22 excerpts from previous works and fused these into a single definition that emphasizes the importance of Service Level Agreements (SLA) in order to increase confidence in the cloud environment and defines virtualization as the key enabler of cloud computing. [Hill et al., \(2013\)](#) gives a recent definition of cloud computing that presents cloud computing as a utility.

Service Models

Cloud services can be classified into three main models:

- Infrastructure as a Service (IaaS): this service mode includes servers (typically virtualized) with specific computational capability and/or storage. The user can control all the storage resources, operating systems and applications deployed to, while he/she has limited control over the network settings. An example is Amazon's Elastic Compute Cloud (EC2), which allows the user to create virtual machines and manage them, and Amazon Simple Storage Service (S3), which allows to store and access data, through a web-service interface.

- Platform as a Service (PaaS): it allows the development, installation and execution on its infrastructure of user-developed applications. Applications must be created using specific programming languages, libraries and tools supported by the provider that constitute the development platform provided as a service. An example is Google Apps Engine, which allows to develop applications in Java and Python and provides for both languages the SDK or Microsoft Azure.
- Software as a Service (SaaS): customers can use the applications provided by the cloud provider. The applications are accessible as web-services through a specific interface. Customers do not manage the cloud infrastructure or network components, servers, operating systems or storage.

Delivery Models

Cloud services can be made available to users in different ways. In the following, a brief description of the delivery models is presented:

- Public cloud: public cloud services are offered by vendors who provide the users/customers the hardware and software resources of their data centers. Examples of public clouds are Amazon (Amazon EC2 provides computational services, such as Amazon S3 storage services); Google Apps (which provides software services like Gmail, Google Docs or Google Calendar, and development platform like Google App Engine); and Microsoft Azure, that is a cloud computing platform and infrastructure, created by Microsoft, for building, deploying and managing applications and services through a global network of Microsoft-managed datacenters. It provides both PaaS and IaaS services and supports many different programming languages, tools and frameworks, including both Microsoft-specific and third-party software and systems.
- Private cloud: private cloud is configured by a user or by an organization for its exclusive use. Services are supplied by computers that are in the domain of the organization. To install a private cloud, several commercial and free tools are available, Eucalyptus, Open Nebula, Terracotta and VMWare Cloud.
- Community cloud: it is an infrastructure on which are installed cloud services shared by a community or by a set of individuals, companies and organizations that share a common purpose and that have the same needs. The cloud can be managed by the community itself or by a third party (typically a cloud service provider).
- Hybrid cloud: the cloud infrastructure is made up of two or more different clouds using different delivery models, which, while remaining separate entities, are connected by proprietary or standard technology that enables the portability of data and applications.

Bioinformatics Cloud-Based Services

The cloud computing represents a cost-effective solution for the problems of storing and processing data in the context of bioinformatics. Thanks to the progress of high-throughput sequencing technologies, there was an exponential growth of biological data. Therefore, classical computational infrastructure for data processing have become ineffective and difficult to maintain (Schadt *et al.*, 2011; Grossmann and White, 2011).

The traditional bioinformatics analysis involves downloading of public datasets (e.g., NCBI, Ensembl), installing software locally and analysis in-house. By entering the data and software in the cloud and providing them as a service, it is possible to get a level of integration that improves the analysis and the storage of bioinformatics big-data (Calabrese, 2015b; Dai *et al.*, 2012). Thus, bioinformatics research institutes no longer have to invest money in costly infrastructures to run expensive scientific analysis (Dudley *et al.*, 2010).

In recent years, several cloud-based tools (Software as a Services, SaaS) to execute different bioinformatics tasks, such as genomics analysis, sequences alignment, gene expression analysis, have been developed (Agapito *et al.*, 2017). A bioinformatics Platform as a Service (PaaS), unlike SaaS, allows the users to customize the deployment of their solutions and to completely control their instances and associated data. Currently, different Cloud-based platforms are available to researchers (Henry *et al.*, 2014). A bioinformatics Infrastructure as a Service (IaaS) model is offered in a computing infrastructure that includes servers (typically virtualized) with specific computational capability and/or storage.

Bioinformatics Platforms Deployed as PaaS

In the following section, the main features and functionalities of specific bioinformatics platforms are discussed. They use Hadoop MapReduce implementation for parallelization (O'Driscoll *et al.*, 2013). MapReduce algorithm splits large inputs for independent processes and then combines the results with HDFS (Hadoop Distributed File System).

Currently, the most used platform (PaaS) for bioinformatics applications is CloudMan (Afgan *et al.*, 2011). It is a public Galaxy Cloud deployment on AWS (Amazon Web Services) cloud; it is, also, compatible with Eucalyptus and other clouds. Galaxy is a bioinformatic platform that collects the main services and tools for several bioinformatics analysis, providing a simple user-friendly interface. CloudMan (see Relevant Websites section) is a CloudManager that orchestrates all of the steps required to the provision, configuration, management and sharing Galaxy on a cloud computing infrastructure, using a web browser. CloudMan combines advantages of Galaxy framework and the benefits of cloud computing model such as elasticity, and pay as you go (Afgan *et al.*, 2012).

cl-dash (see Relevant Websites section) is a complete framework that allows to researchers a quick setup of a Hadoop computing environment in AWS cloud environment. Critical features of the tool include rapid and simple creation of new clusters of different sizes, flexible configuration and custom software installation, data persistence during intermittent usage and low cost of initial investment and during operation (Hodor *et al.*, 2016).

DNAxenus (see Relevant Websites section) allows next-generation sequence (NGS) analysis and visualization. DNAxenus is a cloud-based solution to manage specific genomic data. User can create projects, share them with other DNAxenus users at various access levels, run apps and analysis and build a workflow.

CloudGene (see Relevant Websites section) is an open source platform to improve the usability of MapReduce programs in bioinformatics (Schönherr *et al.*, 2012). Cloudgene provides a graphical user interface for the execution, the import and export of data and the reproducibility of workflows on in-house (private clouds) and rented clusters (public clouds). The aim of Cloudgene is to build a standardized graphical execution environment for currently available and future MapReduce programs, which can all be integrated by using its plug-in interface.

CloudDOE (see Relevant Websites section) is a platform-independent software package implemented in Java. CloudDOE encapsulates technical details behind a user-friendly graphical interface, thus liberating scientists from having to perform complicated operational procedures. Users are guided through the user interface to deploy a Hadoop cloud within in-house computing environments and to run applications specifically targeted for bioinformatics (Chung *et al.*, 2014).

Arvados (see Relevant Websites section) is a platform for storing, organizing, processing, and sharing genomic and other big data. The platform is designed to make it easier for data scientists to develop analyses, developers to create genomic web applications and IT administrators to manage large-scale compute and storage genomic resources. Functionally, Arvados has two major sets of capabilities: (a) data management and (b) compute management. The data management services are designed to handle all of the challenges associated with storing and organizing large omic data sets. The compute management services are designed to handle the challenges associated with creating and running pipelines as large scale distributed processing jobs.

Eoulsan (see Relevant Websites section) is a framework based on the Hadoop implementation of the MapReduce algorithm, dedicated to high throughput sequencing data analysis on distributed computers (Jourden *et al.*, 2012). Specifically, it has been developed in order to automate the analysis of a large number of samples at once, simplify the configuration of the cloud computing infrastructure and work with various already available analysis solutions.

Closing Remarks

Omics disciplines are gaining an increasing interest in the scientific community due to the availability of high throughput platforms and computational methods which are producing an overwhelming amount of omics data. The increased availability of omics data poses new challenges both for the efficient storage and integration of the data and for their efficient preprocessing and analysis. Cloud computing is playing an important role in all steps of the life sciences research pipeline, from raw data management and processing, to data integration and analysis, up to data exploration and visualization.

Cloud-Based Molecular Modeling Systems

Barbara Calabrese, University “Magna Graecia”, Catanzaro, Italy

© 2019 Elsevier Inc. All rights reserved.

Introduction

Molecular modelling is based on the development of theoretical and computational methodologies, to model and study the behaviour of molecules, from small chemical systems to large biological molecules and material assemblies. The application fields of molecular modelling regard computational chemistry, drug design, computational biology and materials science. The basic computational technique to perform molecular modelling is simulation. Molecular simulation techniques requires specific additional computational and software requirements (Ebejer *et al.*, 2013).

Cloud computing could be used by computational scientists and engineers as a means to run molecular simulations and analysis tasks (Xu *et al.*, 2015). Running molecular simulation and analysis tasks in the Cloud could significantly lower the costs of molecular modelling analysis. The cloud computing model provides researchers the use of pay-on-demand computational equipment by a third-party (cloud provider), accessed through an Internet connection (Calabrese and Cannataro, 2015).

Cloud computing model guarantees scalability advantage because computing resources can be allocated dynamically according to the specific needs of molecular simulation projects. For medium size and little size research centres and/or companies, this issue is fundamental because as soon as the project is done, the cloud resources can be deallocated, avoiding the usage and maintenance of highly costly cluster installed locally. In fact, before, massive simulations were prohibitive due to very long run times (in the order of months) and because of the high cost to establish and maintain powerful computational equipments. In PaaS and SaaS solutions, cloud providers are responsible of maintenance and updating.

The use of cloud computing for molecular modelling applications is still in its infancy, because in order to use cloud computing, however, many technical tasks must be performed by the user such as configuring the compute nodes, installing the required software, and launching, monitoring and terminating the computation (Wong and Goscinski, 2012). Other bottleneck is the waiting time to push the data into the cloud. To overcome this limit, data and services could be pushed together on the cloud. In the last years, several SaaS front-ends that facilitate the use of cloud computing have been proposed.

Molecular Modelling Tasks

Molecular modelling and simulation imply a multi-step process and combine different analysis methods. Modelling can help scientists at many levels, from the precisely detailed quantum mechanics and classic molecular modelling to process engineering modelling.

In the following, some of the typical molecular modelling analysis are listed: for each class of analysis, an example of software system is described.

Ab initio protein structure modelling: Ab initio folding (or free-modelling, FM) in protein structure prediction refers to build 3D structure models without using homologous structures as templates. Although many efforts have been devoted to the study of the folding of protein structures based on physics-based force fields, including molecular dynamics simulations that determine each atom's position based on Newton's laws of motion, the most efficient approach for FM structure prediction still exploits the knowledge and information derived from the Protein Data Bank (PDB) library (Berman *et al.*, 2000) and sequence databases (Xu and Zhang, 2012).

QUARK (see “Relevant Websites section”) is an example of computer algorithm for ab initio protein structure prediction and protein peptide folding, which aims to construct the correct protein 3D model from amino acid sequence only (Xu and Zhang, 2011). QUARK models are built from small fragments (1–20 residues long) by replica-exchange Monte Carlo simulation under the guide of an atomic-level knowledge-based force field. QUARK was ranked as the No 1 server in Free-modelling (FM) in CASP9 and CASP10 experiments. Since no global template information is used in QUARK simulation, the server is suitable for proteins that do not have homologous templates in the PDB library (Zhang *et al.*, 2016).

Remote homology detection: In computational biology, protein remote homology detection is the classification of proteins into structural and functional classes given their amino acid sequences, especially, with low sequence identities (Chen *et al.*, 2016). Protein remote homology detection is a critical step for basic research and practical application, which can be applied to the protein 3D structure and function prediction.

HHpred (see “Relevant Websites section”) is a fast server for remote protein homology detection and structure prediction and is the first to implement pairwise comparison of Hidden Markov Models (HMMs) profiles (Söding *et al.*, 2005). It allows to search a wide choice of databases, such as the PDB, SCOP (Structural Classification of Proteins) (Murzin *et al.*, 1995), and Pfam (Finn *et al.*, 2016). It accepts a single query sequence or a multiple alignment as input. Within only a few minutes it returns the search results in a user-friendly format similar to that of PSI (Position Specific Iterated)-BLAST (Altschul *et al.*, 1997).

Fragment-based protein structure modelling: Computational methods for protein structure prediction include: (i) Simulated folding using physics-based or empirically-derived energy functions, (ii) construction of the model from small fragments of known

structure, threading where the compatibility of a sequence with an experimentally- derived fold is determined using similar energy functions, and (iii) template-based modelling, where a sequence is aligned to a sequence of known structure based on patterns of evolutionary variation. Template-based modelling has become the most reliable and used techniques in the molecular modelling field, for three main reasons: (i) The development of powerful statistical techniques to extract evolutionary relationships from homologous sequences; (ii) the enormous growth in sequencing projects which provides the raw information; and (iii) the power of computing to process large databases with a fast turn-around.

Today, the most widely used and reliable methods for protein structure prediction rely on some method to compare a protein sequence of interest to a large database of sequences, construct an evolutionary/statistical profile of that sequence, and subsequently scan this profile against a database of profiles for known structures.

Phyre and *Phyre2* (Protein Homology/AnalogY Recognition Engine; pronounced as ‘fire’) are web-based services for protein structure prediction that are free for non-commercial use. *Phyre* is among the most popular methods for protein structure prediction. Like other remote homology recognition technique, it is able to regularly generate reliable protein models when other widely used methods such as PSI-BLAST cannot. *Phyre2* (see “Relevant Websites section”) is the successor of *Phyre* and it was launched in January 2011. *Phyre2* is one of the most widely used protein structure prediction servers and serves approximately 40,000 unique users per year, processing approximately 700–1000 user- submitted proteins per day. *Phyre2* has been designed to ensure a user-friendly interface for users inexperienced in protein structure prediction methods (Kelley *et al.*, 2015).

Macromolecular visualization: Visualization of macromolecular structure in three dimensions is becoming ever more important for understanding protein structure-function relationship, functional consequences of mutations, mechanisms of ligand binding, and drug design (Krawetz and Womble, 2003).

VMD (Visual Molecular Dynamics, see “Relevant Websites section”) is designed for modelling, visualization, and analysis of biological systems such as proteins, nucleic acids, lipid bilayer assemblies, etc. (Humphrey *et al.*, 1996). It may be used to view more general molecules, as VMD can read standard Protein Data Bank (PDB) files and display the contained structure. VMD provides a wide variety of methods for rendering and coloring a molecule: simple points and lines, CPK spheres and cylinders, licorice bonds, backbone tubes and ribbons, cartoon drawings, and others. VMD can be used to animate and analyze the trajectory of a molecular dynamics (MD) simulation. In particular, VMD can act as a graphical front end for an external MD program by displaying and animating a molecule undergoing simulation on a remote computer.

UCSF Chimera (see “Relevant Websites section”) is another example of highly extensible program for interactive visualization and analysis of molecular structures and related data, including density maps, supramolecular assemblies, sequence alignments, docking results, trajectories, and conformational ensembles (Pettersen *et al.*, 2004). High-quality images and animations can be generated. Chimera includes complete documentation and several tutorials, and can be downloaded free of charge for academic, government, nonprofit, and personal use. Chimera is developed by the Resource for Biocomputing, Visualization, and Informatics (RBVI), funded by the National Institutes of Health.

Molecular dynamics: Molecular dynamics (MD) is a computer simulation method for studying the physical movements of atoms and molecules. The atoms and molecules are allowed to interact for a fixed period of time, giving a view of the dynamic evolution of the system.

NAMD (see “Relevant Websites section”) is a parallel molecular dynamics code designed for high-performance simulation of large biomolecular systems. Based on Charm++ parallel objects, NAMD scales to hundreds of cores for typical simulations and beyond 500,000 cores for the largest simulations (Phillips *et al.*, 2005). NAMD uses the popular molecular graphics program VMD for simulation setup and trajectory analysis, but is also file-compatible with AMBER (see “Relevant Websites section”) (Salomon-Ferrer *et al.*, 2013; Case *et al.*, 2005) and CHARMM (see “Relevant Websites section”) (Brooks *et al.*, 2009). NAMD is distributed free of charge with source code.

Cloud-Based Services for Molecular Modelling Tasks

One of the most sophisticated SaaS for cloud computing is provided by commercial providers such as Cycle-Cloud (cyclecomputing.com), which offers clusters with preinstalled applications that are widely used in the bioinformatics, proteomics, and computational chemistry areas. The most interesting ones, from a molecular modelling perspective, are: (i) Gromacs (Pronk *et al.*, 2013), to perform molecular dynamics (MD) simulations and energy minimization, and (ii) ROCS to perform shape-based screening of compounds. The idea is that molecules have similar shape if their volumes overlay well and any volume mismatch is a measure of similarity.

The Rosetta software suite (see “Relevant Websites section”) includes algorithms for computational modelling and analysis of protein structures. It has enabled notable scientific advances in computational biology, including de novo protein design, enzyme design, ligand docking, and structure prediction of biological macromolecules and macromolecular complexes. A Seattle biomedical software company named Insilicos announced in the 2012 the formation of RosettaATCloud LLC, a joint venture with the University of Washington, that developed Rosetta@cloud, which offers the Rosetta software suite as a cloud-based service hosted on Amazon Web Services. Rosetta@cloud was a startup that offered affordable, cloud-based pay-per-use molecular modelling and related services to the biotech and pharmaceutical industry. It is now inactive.

AutoDockCloud (Ellingson and Baudry, 2014) is a workflow system that enables distributed screening on a cloud platform using the molecular docking program AutoDock. AutoDockCloud is based on the open source framework Apache Hadoop, which

implements the MapReduce paradigm for distributed computing. In addition to the docking procedure itself, preparation steps, such as generating docking parameters and ligand input files, can be automated and distributed by AutoDockCloud.

Acellera (see "Relevant Websites section") announced AceCloud, that is a commercial on-demand GPU cloud computing service. The optimization of MD simulation packages for running on GPUs, such as Amber, Gromacs (see "Relevant Websites section"), LAMMPS (see "Relevant Websites section"), and NAMD is reported to result in large performance increases compared to calculations run on CPUs. AceCloud is designed to free the users from the constraints of their workstation and – though the use of cloud computing technology (specifically, Amazon Web Services) – allows to run hundreds of simulations as easily as running one without the need of any additional setup. The AceCloud interface abstracts all interactions with the supporting cloud computing infrastructure. It emulates the experience of running cloud molecular dynamics locally on one's own machine. AceCloud provides transparent execution of ACEMD (Amber, Charmm inputs) and Gromacs MD simulations. It has a built-in mechanism by which the user may run arbitrary code (such as NAMD and Amber) on an AceCloud instance.

A software plugin for VMD has been developed that provides an integrated framework for VMD to be executed on Amazon EC2, facilitating MD simulations of biomolecules using the NAMD program. This plugin allows use of the VMD Graphical User Interface to: (1) Create a compute cluster on Amazon EC2; (2) submit a parallel MD simulation job using the NAMD software; (3) transfer the results to the host computer for post-processing steps; and (4) shutdown and terminate the compute cluster on Amazon EC2.

Another SaaS example for MD is NCBI Blast (see "Relevant Websites section") on Windows Azure, that is a cloud-based implementation of the Basic Local Alignment Search Tool (BLAST) of the National Center for Biotechnology Information (NCBI). e-Science Cloud is a cloud based platform for data analysis developed at Newcastle University (Hiden *et al.*, 2013).

Closing Remarks

The adoption of cloud computing model in molecular modelling could guarantee several benefits to MD researchers, thanks to computational and storage resources allocated elastically and on demand.

Introduction

Sharing health data can result in many advantages for patients, doctors, researchers, and medical institutions. Experiences like that of [Wicks et al. \(2010\)](#) show that patients can share data about symptoms, treatments, and health in order to learn from the experience of others and improve their outcomes. But the field in which the existence of platforms allowing world-wide sharing of medical data has the most potential benefit, is certainly research, as sharing research data can improve public health. As stated in [Walport and Brest \(2011\)](#), this can help to achieve both immediate and long-term goals. Among the immediate consequences, there is the possibility of setting standards of data and procedure management, so that research and clinical protocols can be routinely shared and effectively reused. Among the long-term benefits, we have to consider the availability of data for extensive analysis, also exploiting correlations with many attributes and features, as location, ethnic characteristics, habits, etc.

However, the ethical aspect plays a crucial role in this process. Indeed, the privacy of individuals as well as the dignity of communities must be carefully protected, as health data represent the most sensitive information in the person's sphere.

From the technological point of view, the cloud is the only possible response to the demand of sharing health data (consider the features of scalability, multilaterality, elasticity, availability, security, etc., required in this case). However, this opens a number of issues that must be dealt with, because it is not possible to exploit only trusted cloud providers. Indeed, the main stakeholders in this sector are private, and it is very difficult for even e-government services to forgo the outsourcing paradigm.

Therefore, security should be guaranteed against the cloud provider, whose full trustworthiness cannot be assumed.

The structure of this article is the following. In Section "Related Work", we discuss the related literature. In Section "The Problem of Privacy in the Cloud", we describe the problem of privacy in the cloud by presenting the main issues arising in this context. Among these issues, Section "The Problem of Access Linkage" focuses on a specific problem that is very relevant when the cloud delivers health services. A possible solution of this problem and its security analysis is presented Section "Proposed Solution". Finally, in Section "Conclusion", we draw our conclusion.

Related Work

The use of cloud-based approaches in medical applications is not new. [Pardamean and Rumanda \(2011\)](#) integrated conducted research on the implementation of cloud computing in health care organizations, focused on an integrated patient medical record information system using a health care standard information format for data exchange. This study was motivated by the fact that health care organizations use a variety of IT applications and infrastructure which always need to be updated as a result of rapid growth in health care services. The diversification of how health care organizations maintain their operations, especially with respect to how they maintain patient medical information caused difficulty with accessing patient's data. They concluded that the use of cloud computing in the Electronic Medical Record (EMR) design, in which leveraging common international health care standards enables integration among many types of health care organizations, whether they already have an application or want to develop a new one. Moreover, they observed that this can reduce complex business processes by automating manual processes.

[Yang et al. \(2010\)](#) implementation discussed the challenge in Medical Image exchanging, storing and sharing issues of EMR and presented a system called MIFAS (Medical Image File Accessing System) to solve the challenges of exchanging, storing and sharing medical images across different hospitals issues. Through this system, they enhanced the efficiency of sharing information between patients and their caregivers.

The problem of privacy when storing electronic medical records has been highlighted by [Li et al. \(2011\)](#). According to the definition set out in the Health Insurance Portability and Accountability Act (HIPPA), the confidential section of the electronic medical record needs to be protected. Thus, a mechanism to protect the patient's privacy is needed during electronic medical record exchange and sharing. The privacy protection mechanism can be categorized into four types, namely anonymity, pseudonymity, unlinkability, and unobservability. Typically, mathematical conversions and cross-reference tables have been utilized to conceal the confidential part of the electronic medical record in order to achieve privacy protection. However, these methods are harder to use than the unlinkability and unobservability mechanisms. [Li et al. \(2011\)](#) tried to improve the unlinkability mechanism between patient identity and the electronic medical record through cloud computing. According to this approach, the electronic medical record system in a hospital can be integrated, to facilitate the exchange and sharing of electronic medical records, and to provide smaller hospitals or clinics that have fewer resources with adequate electronic medical record storage space.

Starting from the observation that cloud computing paradigm is one of the most popular health infrastructures for facilitating electronic health record (EHR) sharing and EHR integration, [Zhang and Liu \(2010\)](#) discussed important concepts related to EHR sharing and integration in healthcare clouds and analyzed the security and privacy issues arising in access and management of

EHRs. Then, they described an EHR security reference model for managing security issues in healthcare clouds, which highlights three important core components in securing an EHR cloud. They also illustrated the development of an EHR security reference model through a use-case scenario, and described the corresponding security countermeasures and state-of-art security techniques that can be applied as basic security measures.

Radwan *et al.* (2012) focused on the importance of healthcare information technology in mobile, web, desktop, and enterprise e-health applications. They observed that the interoperability and data exchange between e-health applications and Health Information Systems (HIS) resulted in increased concerns for securing sensitive data and data exchange, and emphasized the importance of standardizing a data exchange mechanism and interoperability between HISs and e-health applications across a cloud-based service. The proposed service provides a single entry point for retrieving EMR from the various HISs in which a patient record is stored, and for any e-health application seeking such information. The authors also proposed a unified secure platform that allows developers, health care providers, and organizations access to a framework that support retrieving and management of medical records and Personal Health Records (PHR) among various subscribers. The proposed service and platform have been qualitatively evaluated by a sample of physicians, patients, and hospital administrators in a real case study.

In Liöhr *et al.* (2010), several shortcomings of e-health solutions and standards are pointed out, and, in particular, the fact that they do not address client platform security, which is a crucial aspect for the overall security of e-health systems. To fill this gap, the authors of this work defined an abstract model of e-health clouds, which comprises the common entities of healthcare telematics infrastructures. Based on this model, three main problem areas for security and privacy are outlined, which are data storage and processing, management of e-health infrastructures, and usability aspects for end-users. Then, they presented a security architecture for privacy domains in e-health systems, which extends the protection of privacy-sensitive data from centrally managed secure networks to the client platforms of the end-users. For each application area, a separate privacy domain is established and enforced both centrally and locally on each platform.

Although many works deal with the security aspects of cloud computing, few papers have focused on anonymous authentication. Malina and Hajny (2013) dealt with user anonymous access to cloud services and proposed a solution that provides registered users with anonymous access to cloud services. This solution offers anonymous authentication, meaning that users' personal attributes (age, valid registration, successful payment) can be proven without revealing users' identity. Thus, users can benefit from services without any threat of their behavior being profiled. Moreover, if users break the provider's rules, their access rights are revoked. This solution, which is based on a non-bilinear group signature, is not scalable because, when the number of users increases, the size of signature becomes too high, making this solution inefficient in many application contexts.

The recent study of Khan (2016) analyzed and classified the working mechanisms of the main security issues and the possible solutions that exist in the literature, focusing on trusted cloud computing and mechanisms for regulating security compliance among cloud service providers.

Pritam and Chatterjee (2016) proposed an encryption scheme that incorporates cryptographic approaches with role-based access control and also an anonymous control scheme to address the issue of data privacy as well as user identity privacy in access control schemes. A real-time method is provided to maintain a secure communication in cloud computing, which ensures security and trust-based access to cloud. The proposed model contains algorithms to explain data protection and user authentication problems. Their analysis suggested that the purpose of this work is to decrease cloud computing security concerns such as data protection, authentication, and securing data during communication.

All the techniques described above do not consider that the cloud provider may still associate service requests with the IP address of the user, thus linking different user requests and inferring more information. To the best of our knowledge, our proposal is the first one to consider such an attack and to provide a solution. The solution we propose leverages a P2P network for the IP obfuscation.

The Problem of Privacy in the Cloud

The security problems in cloud computing can be faced by following the classical CIA paradigm that consists of a set of rules to guarantee confidentiality, integrity, and availability. Being interested in the privacy problem, we focus our attention on the property of confidentiality. Confidentiality requires that data stored in the cloud can be accessed only by authorized people. Furthermore, the identity of a user accessing the cloud and his actions should be kept secret. Currently, many providers guarantee confidentiality only with respect to third parties but, there are many situations in which it is necessary that data are maintained confidential to the providers themselves.

When it is not possible to assume the trustworthiness of the cloud provider (because it may be malicious or simply curious), we need to apply some confidentiality mechanism.

A simple solution is to encrypt data before storing them in the cloud: if the provider does not know the encryption key, then data cannot be accessed.

Another solution is based on fragmentation. The idea is that data are not sensitive singularly but become sensitive if associated with other information. For example, the attributes NAME and ILLNESS are not sensitive per se but they become sensitive when linked each other (we do not want to declare which illness a person suffers from). Fragmentation enforces that these attributes are stored in different unlinkable fragments. Fragmentation can be used in combination with encryption (Ciriani *et al.*, 2010). For example, in a *two can keep a secret* approach, data are split into two fragments stored in two different databases belonging to non-communicating providers. Only attributes that are sensitive by themselves are encrypted.

Unfortunately, this approach presents some drawbacks. For example, when a user asks for some information and performs a query involving data values, if they are encrypted, it can be difficult for the cloud provider to resolve the query. Actually, cryptographic techniques exist that allow users to perform queries directly on encrypted data (see for example [Hacıgümüş et al., 2007](#)). But, generally, their computational effort is very high. A different approach is presented in [Di Vimercati et al. \(2014\)](#), which introduces indexes on encrypted data to perform queries. There are three types of index: direct index (there is a one-to-one correspondence between data in plaintext and index value), bucket-based-index (there is a many-to-one correspondence between data in plaintext and index value), flattened index (there is a one-to-many correspondence between data in plaintext and index value). However, these techniques are effective against static observation (observation of data stored in the database) but they do not guarantee enough protection against dynamic observation (observation of the queries). In fact, if an attacker observes a long enough sequence of queries, the mapping between index value and plaintext value can be inferred.

Another challenge in a cloud environment is related to the fact that users may have different levels of access to data (some user can access only to certain resources). A possible solution is to encrypt resources by using different keys depending on the level of access. Theoretically, a user should have a different key for each resource he can access, but if the number of resources is too high, it is an impracticable solution. So, it exists the *key derivation method* in which there is a single key per user, some upper level key and public tokens. Each user is able to derive an upper level key that allows him to access resources (or to derive another upper level key) by using his key and public tokens. The disadvantage of this approach is that, if the access policy changes, all keys must be changed. Another solution is proposed in [Di Vimercati et al. \(2007\)](#) and consists in applying two levels of encryption (a first level by user and a second level by provider) and a user that would to access data should pass both the levels.

As mentioned above, confidentiality does not refer to only privacy of data but also to the users who access to data. For example, a user may ask the provider for some information but the provider may not have this information, so it has to recover, transparently to the user, the data from another provider (collaboration between providers), and for this, the first provider should not provide information on the identity of the user to second provider.

In the literature, there are some anonymous techniques, such as attribute-based techniques, that allow users to access their data without revealing their identity, by using a *credential* that ensures users have the right of access. Instead, regarding the privacy of actions that users perform in the cloud, the challenge is to guarantee *access confidentiality* (the provider should not know the specific data which a user accesses) and *patter confidentiality* (the provider should not know if a user accesses two times to the same data). Private Information Retrieval (PIR) techniques are proposed to accomplish this. These techniques consider the database as a string of bits in which a user requests the *i*-th bit in the string, but the server ignores the position of this specific bit. To save computation, [Di Vimercati et al. \(2011\)](#) proposed the introduction of *shuffle indexes* that combine encryption to guarantee data confidentiality and shuffling to guarantee access and pattern confidentiality. Shuffling consists of changing, dynamically at each access, the physical location where data are stored.

A common approach that can be used, transparently, for all techniques, is to add some fake data in order to create confusion, in such a way that an attacker cannot distinguish fake data from real data. Furthermore, the fake information can be used in a probabilistic approach to ensure the trustworthiness of provider ([Xie et al., 2007](#)). Two other features that providers have to guarantee are an adequate level of isolation between data belonging to different users (e.g., if a user stores data influenced by virus, these virus should not be transferred to other data) and deletion confirmation (if a user deletes his data, no copy of them has to remain in cloud).

In general, privacy problems can be much more frequent in virtualization contexts, if the hypervisor does not guarantee the correct allocation and unallocation of resources to different users. Cloud computing is not just about storing data but it is also used by users to communicate with each other. In this case, even if an attacker does not intercept the message, he may infer some information from the knowledge of the identity of users or from the knowledge of the frequency of service invocation.

The challenges described so far concern technical problems in the cloud, but there are also other aspects that have to be considered. One of these is the location where data are stored, which is transparent to users. In some Countries, privacy laws are less strict than others so the Governments of these Countries may access data without the authorization of users. Again, financial problems may also occur if the provider, suddenly, goes out of business and the recovery of data may be difficult. Finally, regardless of what logical techniques providers use, they have to protect the physical location where data are stored. Although these problems may not be very significant for private users, they have a key role for companies or government organization.

The Problem of Access Linkage

Among all the challenges discussed in the previous section, here we focus on the problem related to the trustworthiness of the Cloud provider. We recall that same cloud provider may deliver very different services that have been outsourced by different parties. In a critical health service, we can imagine that strong measures are adopted, also based on cryptography, to protect both the content of processed data and user identity ([Wang et al., 2012](#); [Chaum and Van Heyst, 1991](#); [Malina and Hajny, 2013](#); [Li et al., 2013](#)). But, other services can be supplied to the same user with low or no protection measures including transactions that may reveal the user identity (e.g., a ticket sale service). In this case, an *honest but curious* provider can link the different accesses and thus discover the identity of the user.

The above problem can be better understood by means a real-life example, showing the possible weaknesses deriving from the use of cloud services in sensitive contexts. We assume that a cloud service is used for e-health services (sensitive context) and for flight reservations (typically not a sensitive context). We consider a citizen that connects to a health-care institute of another city,

say C , for a service, and this service is provided by a cloud. In this case, data are sensitive so that they are exchanged in a confidential way and no private information about the citizen is given to the cloud (usually such data are stored in a cyphered way). After this first interaction, the citizen connects to a flight reservation service to book a flight from his city to C (i.e., the city of the health-care institute).

Now, the cloud service provider, which we assume to be *honest but curious*, has the possibility of merging the above cross-domain information and to infer further information, possibly private and sensitive information about the citizen. In particular, by merging the acquired data, the cloud service provider can infer with a high probability, that the citizen has some e-health problem and he will go to the health-care institute of the city C . Moreover, it could even more accurately infer on the citizen's health problem in the case in which the type of health-care institute (e.g., mental hospital, sexual health clinic, or abortion clinic) is known. Clearly, there is also the possibility that this deduction is wrong, for example, because the citizen could be an employee of the health-care provider, but this possibility is less probable and can be excluded by using further information.

It is worth noting that solutions based on anonymous authentication do not solve this problem because the cloud service provider can first link the interaction between the citizen and the health-care institution and then the flight reservation, for example, by the IP address of the citizen requests.

In the next section, we present an approach to solve the above problem by ensuring (i) anonymous authentication, (ii) unlinkability of requests, and (iii) anonymous communication with the cloud service provider.

Proposed Solution

The technique defined in this section (derived by the proposal presented in [Buccafurri et al., 2015](#)), leverages the presence of a government party providing the health service through the cloud. Indeed, this fact makes it realistic to suppose that a trusted third party can be included in the authentication process, in order to simultaneously guarantee anonymity and access unlinkability, but also provide full accountability. The last feature is obviously necessary if we consider both the responsibilities coming from the low requirements of the involved parties and the general need of security against terrorism.

Our solution involves the presence of multiple parties. With no collusion of the involved parties, it is not possible to be aware about the identity of the user accessing the cloud. Accountability is obtained, in case of need, by merging information coming from multiple parties.

Interestingly, besides anonymity of user authentication, unlinkability of user requests is also supported. To do this, we combine a multi-party cryptographic protocol with a cooperative approach based on a Peer-To-Peer network (P2P). We believe that this new way to integrate P2P and cloud computing, in which the customers of the cloud cooperate with each other to obtain privacy features and increased efficiency, is also sustainable from a business point of view, due to the reciprocal advantages obtained by users. Conversely, a solution based on Tor ([Dingledine et al., 2004](#)), such as that proposed by [Laurikainen \(2010\)](#), [Khan and Hamlen \(2012\)](#) appears unrealistic due to legal problems which the subscription to such anonymization system may cause.

The proposed solution relies on a trusted third party to obtain anonymous authentication to a cloud provider. As an additional feature, to avoid the possibility of grouping requests of the same user by linking them to the source IP addresses, we adopt an IP obfuscation strategy based on the use of a private P2P network ([Buccafurri and Lax, 2004](#)).

The entities involved in our model are:

- (i) A cloud provider, P ;
- (ii) A user accessing its services, say U ;
- (iii) A grantor, say G , playing the role of a trusted third party (for instance, a trusted government institution);
- (iv) A set of P2P nodes, called $\mathcal{N}_S$.

As a prerequisite, the grantor and cloud provider must belong to a public key infrastructure so that they can securely interact with each other.

With that said, we are ready to describe our solution for anonymous and unlinkable authentication. As a first step, when a user, U , wants to access a cloud service, he starts an interaction with the grantor, G , and provides his identity and the information about the cloud provider, P , he wants to access. The response of G will contain both a set of *tokens* in the form of bit strings each composed of a *ticket* and a *key*, and the address of a randomly selected node of the private P2P network. U will use this node as an entry point of the P2P network to perform anonymous requests to the cloud provider, P . Each request will be associated with a ticket generated from some secret information known only to G and P . In this way, P can assess the validity of the corresponding token and uses the key to cypher the communication with U for service delivery through the P2P network. Clearly, to prevent P from linking different tokens to the same user, G builds and distributes them randomly. In this way, different requests cannot be linked together and associated with the same user.

We are ready to present our protocol for token generation. It consists of the following steps: registration, identification, and service request.

Registration. In this phase, U interacts with G to exchange all required information for establishing a secure communication channel (e.g., Diffie-Hellman key exchange).

Identification. The user, U , uses the secure channel built during the registration phase to send his identity to G . Furthermore, he specifies the public key certificate corresponding to the cloud provider with which he wants to interact.

Then, G checks the identity of U and his authorizations and produces a set, $\mathcal{TK}_S$, of n tokens as response, along with the address of a P2P node, $A \in \mathcal{N}_S$. Each token contains a pair $(ticket, key)$: more formally, the set of tokens is defined as: $\mathcal{TK}_S = \{(T_i, K_i) : T_i = E^{K_P}(\tau_i || r_i) \wedge K_i = \mathcal{H}(\tau_i || r_i)\}$, with $1 \leq i \leq n$. Here, τ_i is a (long) validity time, r_i is a nonce, K_P is the public key of P , $E^K(x)$ denotes the encryption of x with the key K , $\parallel$ denotes the concatenation operator, and $\mathcal{H}$ is a cryptographic hash function. All the tickets, T_i , are signed by G , so that their authenticity and integrity is guaranteed. Concerning the number of returned tokens, n , we observe that this implicitly establishes the maximum number of requests U can perform during a session. Of course, because the size of a token is very small, we can safely set n to a conveniently large number to decrease the required number of message exchanges between U and G .

As for the entry point, A , of the P2P network, the grantor selects it randomly from a set of the last t users who interacted with the grantor itself. The size t of this set is established by taking the dynamics of the P2P network into account in such a way as to have a suitably high probability that A is present in the network when U contacts it.

Service Request. A request of services to P can be performed once the identification procedure has been carried out. To do so, as a first step, U contacts the entry point, A , to join the P2P network.

Now, at the i -th request, U follows the following steps. First, he generates a secret value, say S , and encrypts it by using a key generated through a function, f , of the i -th key, K_i . This function is pre-agreed among all parties and is used to obtain a considerable change in K_i : typically, f is a cryptographic hash function (e.g., SHA-256). The result of this operation is $c_i = E^{f(K_i)}(S)$. After this, U uses the same procedure above to encrypt the timestamp, t_i , of the current time, thus obtaining a value, $v_i = E^{f(K_i)}(t_i)$.

Now, U is ready to perform a request to P . A request message, m_i , will contain the tuple $\langle T_i, c_i, v_i \rangle$ as credentials and will be delivered to P via the P2P network to obfuscate the originating IP address. As for this aspect, it is worth nothing that there exist several approaches in the literature for addressing this issue (Xu et al., 2003; Riahla et al., 2012). However, for the sake of clarity, we sketch one of the most simplest strategy to achieve this objective. Specifically, when a node of the P2P network receives a message for P , it will decide with a certain probability to deliver this message to P directly or to forward it to another P2P node in its neighbor list. For each message received, every node memorizes the previous hop so that a backwards route is automatically built. This route will be used to deliver the response from P back to the source of the request message. Observe that, the anonymous tunnel through the P2P network created for each request does not allow the cloud provider to link together different tickets of the same user by analyzing the source IP.

As for the reply of P , it runs the following procedure. After verifying the authenticity and integrity of the ticket by means of the public key of the grantor, P uses its private key to decipher T_i and obtains the timestamp, τ'_i , and the nonce, r'_i . Now, it verifies that τ'_i is before the current time, thus checking the temporal validity of this ticket. Moreover, it verifies whether r'_i has been ever received in the past. In the case that either the ticket is expired or r'_i is not valid (already used), this request will be discarded. It is worth noting that, long term temporal validity is useful in case of authorizations with validity time that must be reflected in the credentials sent by G to U .

Then, P obtains the secret value, S , and the timestamp, t_i , by computing $K'_i = \mathcal{H}(\tau'_i || r'_i)$ and using $f(K'_i)$ as the symmetric key to decipher c_i and v_i . Once again, if $t_i + \Delta t$ is less than the current time the request is denied. Observe that, Δt is a security system parameter set to a small value whose utility will be discussed in Section "Security Analysis".

If the request is considered valid, P verifies the validity of the key (i.e., if $K'_i = K_i$). Hence, the response of the provider will be sent through an encrypted communication, obtained using S , established with the anonymous source node of the P2P network.

As a final aspect, we consider the accountability issue. Logs generated by the cloud provider store requests by including the random number of the corresponding credential. This ensures that no information on the user can be obtained with the analysis of these logs. However, log entries can be associated with users' identities by using information stored by G , therefore full accountability is achievable only by merging information owned by both P and G .

Security Analysis

In this section, we discuss the most common types of attack and show how our protocol can withstand them.

Behavior-based deanonymization attack. This kind of attack can be perpetrated if a recurrent pattern in the usage of services during a user authenticated session is found. From the analysis of service logs, an attacker can guess the identity of a user on the basis of his learnt behavior inside the cloud. This attack can be contrasted by using different tickets for each required service. Moreover, the P2P network used to send messages to the cloud service provider adopts a routing protocol that guarantees full anonymity, hence an attacker is not able to correlate requests coming from the same IP address.

Man-in-the-middle attack. In this type of attack, both the provider and the user who accesses the service believe that they are directly communicating with each other. However, the attacker is intercepting and altering or injecting messages exchanged by them during their communication. Our protocol is able to contrast this attack because the secret value, S , used to encrypt the communication channel between P and U cannot be known by the attacker. Moreover, the attacker cannot alter the secret value, S , sent to P in the service request phase because K (which ciphers S) is known by U , and calculated by P . Thus, the attacker is not able to make them believe they are communicating directly to each other (the condition necessary for the success of the attack).

Denial-of-service attack. This type of attack happens when an attacker sends a stream of false requests at the same time to overload and interrupt the service provided by P . Our protocol detects fake requests because they are not signed by the grantor. Moreover, in case a signed message is sent to P more than one time, they will be discarded except for the first one. This attack also fails if it is

combined with a man-in-the-middle attack (this is performed by blocking and collecting a great number of tickets that are then delivered in a single burst), thanks to the ticket expiration time that is suitably set to prevent this possibility.

Replay attack. This type of attack is performed when a valid data transmission (a ticket to access a service in our case) is fraudulently delayed or repeated. Indeed, if the ticket has been already used by the legal owner, it will be detected as not valid thanks to the use of a nonce, r' , in the message. In the case an attacker intercepts the ticket going from user to provider, the expiration time Δt would force the attacker to use it immediately. However, the secret value, S , is necessary to the communication with the provider because the ticket is sent encrypted by $f(K)$. In any case, all the messages between U and P are encrypted by S , hence there is no advantage to the attacker in intercepting and replaying them.

Spoofing attack. The use of a PKI infrastructure for authentication of the grantor avoids the possibility of the attacker of impersonating the grantor in order to obtain the login information of the user.

Password guessing attack. This kind of attack is performed when an attacker tries to obtain user login information in one of the following ways: (i) *off-line*, the adversary guesses a secret (among τ , r , K and S) without the participation of any other party. Although τ is a timestamp, and hence it is easy to know, r is randomly generated and difficult to guess. Also the knowledge of K is hard, because it is a digest computed by a cryptographic hash function. Finally, the secret value, S , is encrypted by $f(K)$, so it is hard to guess without any key knowledge. (ii) *on-line*, submitting possible authentication credentials until the grantor accepts them. As this attack needs the participation of the grantor, it is averted by including a delay in the reply of grantor in order to limit the number of attempts that can be made by the attacker in a certain time.

Conclusion

The Cloud has become an effective tool for collaborative working and information sharing. However, when sensitive data (especially in the field of e-health) and services are involved, many privacy issues arise, because a cloud provider can be honest but curious. In this article, we analyzed this problem from a wide perspective, then focusing on a specific issue, which is the leakage of private information related to the access of users to services delivered by the cloud. Indeed, anonymous access mechanisms do not protect against this adversary situation, when user accesses to critical services are linkable. In this article, we highlighted this problem in the specific field of e-health, showing how the identity of a user can be inferred, thus breaking the privacy of the health service. To address this problem, we propose an authentication scheme supporting anonymity of users and unlinkability of service accesses. This goal is reached by combining a multi-party cryptographic protocol with a cooperative P2P-based approach to access services in the cloud. Moreover, by the cooperation of a trusted third party granting tickets, it is possible to monitor user access, so that users performing illegal actions can be identified.

Introduction

Machine Learning is defined as a computer science discipline where algorithms iteratively learn from observations to return insights from data without the need for programming explicit tests. Machine Learning peaked in Gartner's Hype Cycle for Emerging Technologies in 2017 and received substantial attention in its broader context of Artificial Intelligence (AI) with Google AlphaGo and Tesla Autopilot showcasing the advanced decision-making ability of such techniques.

The recent technological leaps in this space are due to two enabling trends. Firstly, computing is increasingly being shifted into the cloud, which enables the money that has traditionally been spent on hardware to now be invested in computing. This rent-based access results in the use of more powerful and specialized hardware. As machines learn through an iterative process of evaluating and updating internal evaluation measures, performing this on more appropriate systems removes traditional limitations and allows for more sophisticated methods to be trained. Secondly, the digital revolution has seen a dramatic increase in data collection about almost every aspect of life. As the ability of a machine to gain generalizable insights from presented examples is directly correlated with the dataset size, the recent increase has enabled the training of very sophisticated Machine Learning models.

These datasets are not only growing vertically, by capturing more events, but also horizontally by capturing more information about these events. The challenge of "big" and "wide" data is especially pronounced in the biomedical space where, for example, whole genome sequencing (WGS) technology enables researchers to interrogate all 3 billion base pairs of the human genome. With an expected 50% of the world's population likely to have been sequenced by 2025, the resulting datasets may surpass those generated in Astronomy, Twitter and YouTube combined ([Stephens *et al.*, 2015](#)). Machine Learning approaches are hence necessary to gain insights from these enormous and highly complex modern datasets. Here we will discuss applications in sequence annotation, disease gene association, and drug discovery.

Specifically, for analysing next-generation-sequencing data, Machine Learning has been applied to analyse RNA sequencing (RNA-seq) expression data, data from chromatin accessibility assays, such as DNase I hypersensitive site sequencing (DNase-seq), or chromatin immunoprecipitation followed by sequencing (ChIP-seq), and data on histone modification or transcription factor binding, to name a few. For more details, please see the excellent review by [Libbrecht and Noble \(2015\)](#).

Machine Learning approaches have been applied in life science fields well before the genomic revolution. For example, Machine Learning algorithms can learn to recognize patterns in DNA sequences ([Libbrecht and Noble, 2015](#)), such as pinpointing the locations of transcription start sites (TSSs) ([Ohler *et al.*, 2002](#)), identifying the importance of junk DNA in the genome ([Algama *et al.*, 2017](#)), and identifying untranslated regions (UTRs), introns and exons in eukaryotic chromosomes ([Picardi and Pesole, 2010](#)).

Enhancing the annotation of genomic regions can be achieved by using Machine Learning to combine datasets for functional gene annotation. Here, the input data can include the genomic sequence, gene expression profiles across various experimental conditions or phenotypes, protein-protein interaction data, synthetic lethality data, open chromatin data, and ChIP-seq data on histone modification or transcription factor binding ([Libbrecht and Noble, 2015](#)). Specifically transcription factors, as the master regulators of gene expression, have received attention and models have built for profiling their binding behaviour ([Kummerfeld and Teichmann, 2006](#)).

Moving up from two-dimensional sequence space, Machine Learning has also found application in predicting the 3D structure of proteins and RNA molecules from sequence, the design of artificial proteins or enzymes, and the automated analysis and comparison of biomacromolecules in atomic detail ([Hamelryck, 2009](#)).

Moving from descriptive applications to interpretative areas, Machine Learning has been used to gain insights into the molecular mechanisms of genetic diseases and susceptibilities. This is because of the growing awareness that complex interactions among genes and environmental factors are important in common human disease etiology. Traditional statistical methods are not well suited for identifying such interactions, especially when interactions occur between more than two genes, or when the data are high-dimensional (many attributes or independent variables). Machine Learning algorithms, including artificial neural networks (ANNs), cellular automata (CAs), random forests (RF), and multifactor dimensionality reduction (MDR), have been used for detecting and characterising susceptibility genes and gene interactions in common, complex, multifactorial human diseases ([Mckinney *et al.*, 2006](#)). However, the traditional implementations of these technologies reach their limit with modern dataset sizes, which we will discuss in the context of VariantSpark ([O'Brien *et al.*, 2018](#)) in Sections Random Forests (RF) and Feature Selection.

Machine learning techniques have been used to elucidate the functional interactions of genes by modelling and analysing gene regulatory networks ([Schlauch *et al.*, 2017](#); [Ni *et al.*, 2016](#)). This machine learning discipline has helped answer biological questions about how molecular phylogenetics and evolution represents at whole-genome level, about how to identify protein biomarkers of diseases, and for disease-gene association discovery ([Leung *et al.*, 2016](#)).

Finally, arriving at applications in drug discovery, Machine Learning has been specifically applied in proteomics, which is the large-scale analysis of proteins, the main targets of drug discovery. Proteomics research provides applications for drug discovery,

including target identification and validation, identification of efficacy and toxicity biomarkers from readily accessible biological fluids, and investigation into the mechanisms of drug action or toxicity (Blunsom, 2004). Drug discovery is a continuous process that applies a variety of tools from diverse fields. Proteomics, genomics and some cellular and organismic approaches have been developed to accelerate the process (Abu-Jamous *et al.*, 2015a).

This article summarizes two main Machine Learning approaches: supervised learning and unsupervised learning. Apart from these predictive models, which aim to provide one result per sample, we also discuss generative methods, which are aimed at training a model to generate new data with similar properties to the training data. Lastly, we devote a section to Deep Learning, as one of the most recent developments in Machine Learning. However, we first discuss training regimes and quality control, for a more detailed description of this we refer the reader to the review by Libbrecht and Noble (2015).

Dataset for Machine Learning and Performance Measure

Choosing the right dataset is important for building a robust machine learning model. Typically, the dataset is divided into training set, validation set and test set. The training set is applied to build the models; the validation set is adopted to evaluate the generalization error of the final selected model and for optimizing the parameters; the test set is used as the final prove of the model's performance and used to report the generalization ability to unseen data.

Overfitting

In the machine learning task, a learning model is trained on a set of training data, but then it is applied to make predictions on new dataset. We need to consider the general situation that if the knowledge and data we have are not sufficient to completely determine the correct classifier. We take the risk of just constructing a classifier (or parts of this classifier) that is not grounded in reality, and is simply encoding random data points in the dataset (Domingos, 2012). The objective is to maximize its predictive accuracy on the new data set, and not necessary its accuracy on the training dataset. In fact, if we try our best to identify the very best fit to the training dataset, we run the risk of fitting the noise in the data by memorizing various peculiarities of the training data rather than finding a set of general predictive rules. This problem is called "overfitting" (Dietterich, 1995). Overfitting generally happens when the gap between the training and the test error is large (Valiant, 1984).

Domingos provided one way to understand overfitting by decomposing generalization error into bias and variance (Fig. 1). Consider a random guesser that chooses a number from a set of positive numbers irrespective of any input. Such a method will have high variance and high bias. Now if we limit the guesser to only returning the same number, it will have a low variance but is

Fig. 1 Bias and variance in overfitting. Reproduced from Domingos, P., 2012. A few useful things to know about machine learning. Communications of the ACM 55, 78–87.

still biased. Conversely, we can reduce the bias by allowing the function to return positive and negative values. However, if we implement a function that actually takes the input into consideration and accurately predicts the target label, we can reduce both variance and bias.

Training Dataset

The most important consideration for generating a training dataset is to collect samples that span the entire problem space and represent predicted classes or values equally. Typically, it is easy to select samples for the commonly occurring classes or values (majority class). However, a classifier trained on such an imbalanced dataset would likely only predict the majority class. Consider a classifier for lung cancer with 351 patients, of which 95 had reoccurring cancer while 256 were cured. A model predicting no recurrence of lung cancer for all patients would reach an accuracy of 72.93% $(256/351) \times 100$. Despite this deceptively high classification accuracy it would tell 95 patients that their lung cancer was not going to reoccur (False Negatives), which is likely useless for a clinical setting. If the model needs to also accurately predict the minority class then it must have an equal representation of such samples in the dataset.

As collecting more of the minority class can be difficult, and presenting multiple copies of the same sample can lead to artefacts, undersampling the majority class is a common approach for processing imbalanced datasets. However, undersampling data has also drawbacks especially if the dataset is small to begin with. More specialized approaches have been developed taking the mechanisms in the different Machine Learning methods into account, e.g., for SVM (Akbari *et al.*, 2004).

Besides the equal representation of the prediction label (class or value), also important is the unbiased representation of samples. For example, the scenario of including the same sample multiple times can happen involuntarily especially if sample similarity cannot be determined easily (e.g., expression profile). Thorough analysis of the training dataset prior to training a Machine Learning method is hence strongly advisable.

Cross-Validation

Another potential source of bias can be the assignment of samples to training and test data. Any fixed split into training and testing data can lead to bias if the split happens to distribute samples unfavourable, e.g., all minority classes in the test set. N-fold cross-validation is a popular statistical method for randomizing the dataset and creating N equal size partitions: One from the Nth partition is picked for validation/testing, while the remaining N-1 sets are used for training the model then rotating the partitions until all have been used for testing. (Refaeilzadeh *et al.*, 2009).

However, in situations where the similarity between samples is hard to determine, standard N-fold cross validation may not be the right approach. Michiels *et al.* propose a multiple random validation strategy for prediction of cancer from microarrays. This strategy is about identifying a molecular signature (the subset of genes most differentially expressed in patients with different outcomes) in a training set of patients and to evaluate the proportion of misclassifications with this signature on an independent validation set of patients. They applied this strategy based on unique training and validation sets by using multiple random sets to study the stability of molecular signature and the proportion of misclassifications (Michiels *et al.*, 2005).

Measuring Performance of Classification

The use of the area under the receiver operating characteristic (ROC) curve (AUC) are generally used as a performance measure for machine learning algorithm on classification problem (Bradley, 1997). The receiver operating characteristic curve illustrates a binary classifier system as its discrimination threshold is varied. The ROC curve can be plotted with true positive rate (TPR) against the false positive rate (FPR) at various threshold settings from the so-called confusion matrix, which counts the correctly classified (True positives, True negative) as well as incorrect classifications (False positives, False negatives). The area under the ROC curve (AUROC) evaluates the accuracy of the test. An area of 1 represents a perfect test while an area of 0.5 demonstrates a random classifier. The precision-recall curve provides an alternative measure compensating for skewed datasets. The precision is the fraction of relevant instances among the retrieved instances, while recall is the fraction of relevant instances that have been retrieved over the total number of relevant instances. Both AUROC and the area under the precision-recall curve (AUPRC) can be measured using N-fold cross validation from training dataset [Table 1](#).

Two methods, correlation coefficient and root-mean-square error, are commonly applied to measure the performance of Machine Learning algorithms in regression problems. The correlation coefficient quantifies the relationship between the predicted and observed labels and ranges from -1 to $+1$. A value of 0 means no relationship exists between the two continuous variables, and a value of 1 means a perfect relationship, with -1 denoting a perfect anti-correlation. The Pearson correlation coefficient is

Table 1 Confusion matrix

	Positive	Negative
Positive	True positive	False positive
Negative	False negative	True negative

used when both variables are normally distributed, otherwise the Spearman correlation coefficient is more appropriate. The correlation coefficient represents the association, not causal relationships (Mukaka, 2012). The root-mean-square error (RMSE), on the other hand, quantifies the standard deviation of the residuals (prediction errors). The residuals are an indicator of how far from the regression line data points are. RMSE is a frequently used as indicator of the differences between values predicted by a model or an estimator and the values actually observed.

Supervised Learning

Supervised learning can be performed for training datasets where the labels or targets are known for each sample, e.g., the disease status or the category (Maglogiannis, 2007). Think of this as a child-teacher scenario, where the child learns a subject by receiving feedback on the accuracy of the answer he/she gives. Similarly, a supervised model will learn, from the truth provided in the training set, to build a generalized model that can then be applied to predict the labels for new data. The labels can be categorical, such as ethnicity (O'Brien *et al.*, 2018), or continuous, such as survival rates (Shipp *et al.*, 2002). The former case is called classification while the latter is called regression.

The inputs to the model are called features, which are information points that describe the sample, such as an expression or genotype profile. So, a more general statement is that a supervised learning approach identifies a mapping method from one data space (features) to another data space (targets, i.e., labels) (Yang, 2010).

Another subcategory of supervised learning is feature selection. The objective here is to identify the set of features that are most associated with the labels, to either gain insights into the underlying mechanisms (e.g., biological insights) or remove redundant or noisy variables in order to improve accuracy.

In the subsequent sections, we discuss the different methodologies, such as Bayesian networks, trees, random forest, support vector machines, and artificial neural networks in the classification context. However, those technologies can also be applied in regression, which we discuss in a separate section, below.

Classification

Classification is a fundamental task in data analysis and pattern recognition that constructs a classifier, which assigns a class label to an instance with a set of features/attributes. Similarly to categorization (Cohen and Lefebvre, 2005; Frey *et al.*, 2011), classification is a general process for recognizing, differentiating, understanding, and grouping ideas and objects into classes. It has been widely used in computer science, e.g., in natural language processing (Jackson and Moulinier, 2007), prediction, and decision making (Heekeren *et al.*, 2004).

The induction of classifiers from data sets of pre-classified instances, usually called training data, is one of the fundamental tasks in Machine Learning (Stanke and Waack, 2003). The process of modelling from training data, i.e., building up the mapping from observed features/attributes to correctly predict the class from the available data, is called training or learning. Some common classification approaches are Bayesian classification, classification trees, random forest, support vector machines, nearest neighbours, artificial neural networks, ensemble models (combining classifiers), and so on.

Bayesian classification

Bayesian classification is a statistical classification that minimizes the probability of misclassification (Devroye *et al.*, 2013). Many Bayesian classification algorithms are common, and they are traceable to a common ancestor (Langley *et al.*, 1992). They come originally from a supervised algorithm, which is simply referenced as a Bayesian classifier, in pattern recognition (Duda *et al.*, 1973), that assigns a simple probabilistic summary for the data; This summary includes the conditional probabilities of the class labels given the attribute values (Langley *et al.*, 1992; Rish, 2001), which is called the posterior distribution. Bayesian classifiers employ models connecting attributes to class labels and incorporate prior knowledge so that Bayesian inference can be utilized to derive the posterior distribution.

Classification trees

Tree-based algorithms form a decision tree for features in which nodes represent a series of decisions which leaves represent the final class labels. Given an observation with many features, the inference is then by passing those values of features through the decision tree from the top layer to a leave where the prediction is made. Models are constructed by recursively partitioning the feature space, and fitting a simple prediction threshold for each partition. The partitioning is represented graphically as a tree (Loh, 2011). Classification trees are very intuitive in the sense that they can be easily visualized and interpreted. They are also easy to train thanks to their simplicity. The depth of the tree and number of splits in each layer are the main parameters used to curb the overfitting problem.

Random forests (RF)

The random forests (RF) method constructs an ensemble of tree predictors, where each tree is constructed on a subset randomly selected from the training data, with the same sampling distribution for all trees in the forest (Breiman, 2001). Random forest is a

popular nonparametric tree-based ensemble Machine Learning approach that merges the ideas of adaptive nearest neighbour clustering with bagging (Breiman, 1996) for effective data adaptive inference. RF can be applied to “wide” data (“large p, small n”) problems, and accounts for correlation as well as interactions among features (Chen and Ishwaran, 2012). Data are identified as a fixed number of features which can be binary, categorical or continuous. Searching a good data demonstration is very domain specific and related to available measurements (Isabelle, 2006). In our gene editing CRISPR target sites on-target activity example, the features use the measurement of target site sequences, such as position-independent or position-dependent nucleotides and dinucleotides (Wilson, *et al.*, CRISPR Journal accepted).

RF has been used for gene selection and classification of microarray data (Korf, 2004). More recently, RF have been used for predicting CRISPR-Cas9 on-target activities (Wilson *et al.*, CRISPR Journal accepted). The RF model, called TUSCAN, is part of the GT-Scan2 suite for predicting target sites for CRISPR/Cas9 genome engineering. TUSCAN, uses sequence information describing the target site, such as global di-nucleotide frequency, or the presence of nucleotides at specific positions, to predict the activity of any given site. In total 621 features describe each site. For its final model TUSCAN performs feature selection to reduce the number of features to the 63 most important features (see Section Measuring Performance of Classification, Feature selection). TUSCAN can predict the activity of 5000 target sites in under 7 seconds, and is up to 7000 times faster than available methods, and is hence suitable for genome-wide screens.

Support vector machine (SVM)

Support vector machines (SVM) are a pattern classification technique proposed by Vapnik *et al.* (Boser *et al.*, 1992). SVM minimizes an upper bound on the generalization error through maximizing the margin between a hyperplane separating the data classes, and the data (Amari and Wu, 1999). The idea is to transform the data that is not linearly separable in its original space to a higher dimensional space where it can be separated by a simple hyperplane.

SVM has been used to identify target sequences in proteins and nucleic acids, for instance to identify SUMOylation sites (Bauer *et al.*, 2010) in proteins, or splice sites (Degroevae *et al.*, 2002) in primary mRNA. An accurate miR-E shRNA (the improved amiRNA backbone short hairpin RNAs) predictor has been developed using a sequential learning algorithm combining two support vector machine (SVM) classifiers trained on judiciously integrated data sets (Pelossof *et al.*, 2017).

A method has been developed using SVM for classification of tissue samples, consisting of ovarian cancer tissues, normal ovarian tissues and other normal tissues, and an exploration of the data for mislabelled or questionable tissue results. The tissue samples include ovarian cancer tissues, normal ovarian tissues and other normal tissues (Furey *et al.*, 2000).

Artificial neural networks

The motivation for neural networks was originally to mimic the working mechanism of the human brain. It is a graph computing model wherein computing units called neurons are organized in layers, and interconnected for passing information to each other (Kruse *et al.*, 2016). The first layer is the input layer which receives the raw data. The last layer is the output layer, which performs the final prediction task, e.g., classification, regression, and so on. The layers in between are hidden layers. To simplify optimization, the neurons in the same layer are not connected. Neural networks with three layers have the capability to approximate any function. However, the determination of the network architecture is not a trivial task, for example, the number of neurons in hidden layers and their activation functions. What about ANNs with no hidden layer?

Classic feedforward neural networks (FFNN) have been applied to predict protein site-directed recombination, which are breakpoint locations in a protein where introducing sequence from a homolog can yield improved activity (e.g., better heat stability) (Bauer *et al.*, 2006). Convolutional neural networks (CNN) uses a sequence of 2 operations, convolution and pooling, repeatedly on the input data. CNN are a subset of FFNN with a special structure, including sparse connectivity between layers and shared weights, which have surpassed conventional methods in modelling the sequence specificity of DNA-protein binding. In a systematic exploration of CNN architectures for predicting DNA sequence binding using a large compendium of transcription factor dataset, CNNs have been implemented as the best-performing architectures by varying CNN width, depth and pooling designs (Zeng *et al.*, 2016). A combination of embedding-based convolutional features (dense real value vectors, including word’s feature vector and syntax word embedding) and traditional features has been developed for use with a softmax classifier to extract DDIs from biomedical literature for detecting drug-drug interactions (DDI) (Zhao *et al.*, 2016).

Combined classification approaches

The quality of *de novo* sequence assembly can be improved by Machine Learning methods using comparative features, such as N50 score and percent match, and non-comparative features, such as mismatch percentage and the *k*-mer frequencies, to classify overlaps as true or false prior to contig (a set of overlapping DNA segments) construction (Palmer *et al.*, 2010). A comprehensive evaluation of multicategory classification methods has been performed for microarray gene expression cancer diagnosis. The multicategory support vector machines (MC-SVMs) have been demonstrated as the most effective classifiers in performing accurate cancer diagnosis from gene expression data and outperform other popular machine learning algorithms, such as backpropagation and probabilistic neural networks. The classification performance of both MC-SVMs and other non-SVM learning algorithms can be improved significantly by gene selection techniques (Statnikov *et al.*, 2005).

Microbiology is the study of microscopic organisms in numerous sub-disciplines including virology, mycology, parasitology, and bacteriology. In microbiology, it was formerly necessary to grow pure cultures in the laboratory in order to study an organism. Since many organisms cannot be cultured, this created a cultivation bottleneck that has limited our view of microbial diversity.

Metagenomics provides a relatively unbiased view of the community structure (species richness and distribution) and the functional (metabolic) potential of a community (Hugenholtz and Tyson, 2008). Metagenomic methodologies are recognized as fundamental for understanding the ecology and evolution of microbial ecosystems. The development of approaches for pathway inference from metagenomics data is crucial to connecting phenotypes to a complex set of interactions stemming from a series of combined sets of genes or proteins. The role of symbiotic microbial populations in fundamental biochemical functions have been investigated based on the modelled biochemical and regulatory pathways within one cell type, one organism, or multiple species (De Filippo *et al.*, 2012).

Machine Learning methodologies are often used for supervised classification. Feature representations and selection may improve microbe classification accuracy by producing better models and predictions (Ning and Beiko, 2015). Microbial communities are crucial to human health. Beck *et al.* have tested three Machine Learning techniques including genetic programming (GP) (Moore *et al.*, 2007; Eiben and Smith, 2003), random forests (RFs), and logistic regression (LR) for their ability to classify microbial communities into bacterial vaginosis (BV) categories. Before constructing classification models, the microbes were collapsed into groups, based on correlations, by reducing the number of factors, such as environmental variables, or dynamic microbial interactions, and to increase the interpretability of the classification models. Genetic algorithm uses computational simulations of evolutionary processes to explore highly fit models; RF is efficient but may not be as flexible as GP; LR fits a linear model, and produces a linear combination of features and regression coefficients whose value for a given set of microbial communities and patient behaviour quantifies the likelihood that the patient had BV (Beck and Foster, 2014).

Regression

In Machine Learning, regression can be seen as being more general than classification. In regression (except Poisson regression), the labels, i.e., the targets of the model, are continuous quantities, instead of discrete or categorical values. The modelling process here seeks to find a function that maps from feature to target, and which can then be used to predict the labels of new unseen data with some accuracy.

Regression methods attempt to model the relationship between input, the independent variables, and output, the dependent or response variables, by constructing parametric equations in which the parameters are estimated from the training data. The most commonly used regression methods are linear models, which include linear regression (Freedman, 2009), and regularized linear regression (McCullagh, 1984), as well as generalized linear models. Regularized regression methods fit linear models for which the number of coefficients are constrained. Regularized regression methods include ridge regression and the LASSO (Dasgupta *et al.*, 2011).

The LASSO technique was proposed by Tibshirani (1996). The LASSO and sparse least squares regression (SPLS) methods have been used for SNP selection in predicting quantitative traits. The performance in terms of r^2 (the square of Pearson correlation coefficient) for both LASSO and SPLS are almost identical in some scenarios. The LASSO produces a stable model, which is with less coefficients of each variable, because the LASSO method does not consider the effects of the correlation among SNPs, and also tends to reduce the coefficients of each variable with the shrinkage feature (shrink the feature vector) (Feng *et al.*, 2012). LASSO, along with other sparse regression models, shares the property of selecting variables and building the linear model at the same time. However, the caveat is the bias created by the regularization term, in terms of geometry, Bayesian statistics, and convex analysis, in the model.

Feature Selection

Data are demonstrated as a fixed number of features which can be binary, categorical or continuous. Identifying a good data demonstration is very domain specific and related to available measurements (Isabelle, 2006). Feature selection is crucial for the model building when there are many features in the data sampling process. Feature selection has been part of supervised learning in many real-world applications, although it can be applied to unsupervised learning scenarios as well. The high dimensional nature of many modelling tasks in bioinformatics, such as sequence analysis, microarray analysis, spectral analysis, and literature mining, has demanded the development of applications using feature selection techniques (Abu-Jamous *et al.*, 2015b). The goal is to select subset of features that can be used to better classify the given data objects (Abu-Jamous *et al.*, 2015a). A rigorous training and testing schema needs to be applied to find the statistical properties for the training set and test set, without biasing the approach by removing features that generalise well. (Libbrecht and Noble, 2015).

The three main motivations of feature selection are the following. First, to improve the overall accuracy of a prediction method by eliminating noisy or redundant features (Libbrecht and Noble, 2015). Second, to gain insights into the underlying mechanisms, e.g., answering an underlying biological question, such as identifying the genes that are associated with the corresponding functional label in order to gain insights into disease mechanisms (Glaab *et al.*, 2012; Tibshirani, 1996; Urbanowicz *et al.*, 2012). Both reasons were applied in TUSCAN (Wilson *et al.*, CRISPR Journal accepted) with an average AUC of 0.63, where the feature selection reduced the number of uninformative features from 621 to 63, and improved the average Cross-Validation result of the model by 12% to $R=0.6$ ($p<0.05$, t-test), which in turn gave insights into the most predictive features to be important to Cas9 on-target activity, including a Guanine at position 24 (G24), a depletion of Thymine within the seed region (5–12 bases preceding the PAM) and GC content.

However, there is a third motivation, which is adopted due to computational limitations rather than for improving accuracy or gaining insights. That is, to enable a more complicated model to be fitted, which has constraints on the number of features it can

process. Typical examples of this scenario include genome wide association studies (GWAS), where a preliminary feature selection based on linear regression models is performed, followed by a multi-variate model to capture complex interactions (Boyle *et al.*, 2017). The difficulty here is that this selection process can remove features that may individually not be associated with the traits of interest, but would have been major modulating factors in the multi-variate model.

To address this issue, VariantSpark (O'Brien *et al.*, 2018) was developed, which is a RF model implemented on a more powerful compute paradigm (Apache Spark), which overcomes the limitations of traditionally implemented models. VariantSpark allows a multi-variate model to be built directly on the full set of input features, thereby not discarding possibly important features during the feature selection process. It then allows features to be ranked according to their importance, thereby supporting the two main aims of feature selection, namely improving accuracy and gaining insights in the underlying mechanisms.

Unsupervised Learning

In contrast to supervised learning, learning from instances where label information is unavailable or is not used in the modelling process is called unsupervised learning (Maglogiannis, 2007). The purpose of unsupervised learning is to identify patterns in the data, such as finding groups of similar samples or identifying a trend line.

Typically, data collected through automated processes are unlabelled data, where, especially in the life-science space, the data volumes and speed with which the data is changing prevents the creation of an expert annotated subset on which to train supervised methods. As such, extracting information and gaining insights from large volumes of unlabelled data has recently become very important. Here, we will discuss Clustering approaches, such as hierarchical clustering, K-means, and model-based clustering.

Clustering

Clustering aims to group data into categories so that the data in each category share some commonalities or exhibit some uniformity. Clustering is a useful approach, especially in the exploratory data analysis phase, during decision-making, and when serving as a pre-processing step in Machine Learning. Clustering is widely used in data mining, document retrieval and image segmentation (Krogh, 2000). Hierarchical clustering, k-means clustering, and mixture models are the most important clustering families. Cluster assignment is typically quantitative in contrast to statistical dimensionality reduction methods like principal component analysis (PCA) or multidimensional scaling (MDS), where groupings are qualitatively based upon visual inspection in 2 or 3-dimensional space, or more depending on the data.

Hierarchical clustering

Hierarchical clustering builds clusters by recursively partitioning the instances in either a top-down or bottom-up fashion. Hierarchical clustering methods can be divided into two types of clustering methods: agglomerative hierarchical clustering and divisive hierarchical clustering. In agglomerative hierarchical clustering, each object initially represents a cluster of its own, and clusters are successively merged to obtain the desired cluster structure using Ward's method. Ward recommended the criterion for selecting the pair of clusters to merge at each step is based on the optimized value of an objective function, which can be any function that reflects the investigator's purpose (Ward, 1963). In divisive hierarchical clustering, all objects initially belong to one cluster, and this cluster is successively divided into their own sub-clusters to obtain the desired cluster structure (Majoros *et al.*, 2004).

Hierarchical clustering algorithms have been used for gene sequences. A method named Unweighted Pair Group Method using arithmetic Averages (UPGMA) (average linking) is regarded the most widely used algorithm for hierarchical data clustering in computational biology. The entire collection of protein sequences has been automatically built a comprehensive evolutionary-driven hierarchy of proteins from sequence alone using a novel class of memory-constrained UPGMA (MC-UPGMA) algorithms (Loewenstein *et al.*, 2008).

k-means clustering

k-means clustering is a so-called partitional clustering algorithm, where samples for data sets are moved between clusters as the learning progresses. The algorithm begins by randomly selecting k samples and using their coordinates as the centroids (cluster centres). The algorithm then assigns each sample to its nearest centroid. This is based on a distance measure such as the Euclidian distance. Once every sample has been assigned to a centroid, each centroid is shifted to the mean of the samples assigned to that centroid. This process repeats iteratively (assign samples to centroids, adjust the centroids to reflect the mean of assigned samples) until certain stopping criteria are met. These criteria are either a maximum number of iterations, or a threshold defining a distance the centroids must move for them to not yet be considered as converged.

Many k-means implementations allow the user to define the above parameters (the value of k, the maximum number of iterations, and the distance measure). Defining the optimal value for k may be considered especially important, as it defines the number of clusters the algorithm will invariably build. Specifying the correct value for k can be a case of compromise, as increasing this value will decrease one of the error metrics (the within set sum of square error, or WSSSE), but may result in clusters

containing just one sample. One colloquial method to find the optimal value for k is the “elbow method”. This method plots the WSSSE as a function of k . According to this method, the optimal value for k is the point on the graph where the relative decrease in the WSSSE drops for each increase in k (i.e., the “elbow” in the plot).

k -means, as a heuristic algorithm, may not find the global optimum. To find the global optimum in partition-based clustering, an exhaustive enumeration process of all possible partitions is required. However, this is computationally infeasible, and therefore greedy heuristics such as k -means are ideal for these clustering problems (Majoros *et al.*, 2004).

k -means clustering was used in the VariantSpark suite to cluster individuals by their ethnicity based on their genomic profile (O’Brien *et al.*, 2015). When using genome sequencing data, this problem can be challenging as the number of variants across the input data can easily reach millions, even with only a moderate number (100–1000 s) of samples. This is due to many rare variants that are only present in a small set of samples. Because of this sparsity, variant data can be stored as sparse vectors. This is more efficient than using standard feature vectors, as sparse vectors need not store zero-values. Once VariantSpark has transformed variants from text files into sparse vectors, it can then cluster the individuals using the aforementioned K-means algorithm.

Generative Models

In this section we discuss generative models, which aim at generating novel data based on the patterns learned from the training data.

Mixture Models

Mixture models are also known as model-based clustering. Model-based clustering is a broad family of algorithms designed for modelling an unknown distribution as a mixture of simpler distributions, sometimes called basis distributions. The classification of mixture model clustering is based on the following four criteria: (i) the number of components in the mixture, including finite mixture model (parametric) and infinite mixture model (non-parametric); (ii) the clustering kernel, including multivariate normal models, or Gaussian mixture models (GMMs), the hidden Markov mixture models, Dirichlet mixture models, and other mixture models based on non-Gaussian distributions; (iii) the estimation method, including non-Bayesian methods and Bayesian methods; (iv) the dimensionality, including classes of factorising algorithms, such as mixture of factor analysers (MFA), MFA with common factor loadings, mixture of probabilistic principal component analysers, and so on (Abu-Jamous *et al.*, 2015b).

A widely used example of GMMs in bioinformatics is the VariantRecalibrator tool, which is part of the Genome Analysis Toolkit (GATK) (Depristo *et al.*, 2011). GATK is a suite of tools for genomic variant discovery in high-throughput sequencing data. VariantRecalibrator is, in fact, the first part of a two-stage process called VQSR (Variant Quality Score Recalibration). VariantRecalibrator uses GMMs to generate a continuous, co-varying estimate of the relationship between SNP annotations and the probability that a SNP is a genuine variant (versus a sequencing artefact). The GMM is estimated adaptively based on a set of true variants provided from highly validated sources (e.g., HapMap 3 sites, or the Omni 2.5M SNP chip array).

The second stage of VQSR is called ApplyRecalibration. Here, the adaptive GMM generated by VariantRecalibrator can be applied to both known and novel genetic variations discovered in the dataset at hand, thus evaluating the probability that each variant is real. Each variant is then annotated with a score called VQSLOD, which is the log-odds ratio of being a true variant versus being a false variant (sequencing error) under the trained GMM.

Probabilistic Graphical Models

Probabilistic graphical models use a graph-based representation to compactly encode a complex distribution over a high-dimensional space. The nodes correspond to the variables in the domain, and the edges correspond to direct probabilistic interactions between them (Burge and Karlin, 1997). Bayesian networks and Markov networks are important families of graphical representations of distributions.

Bayesian networks

Bayesian networks are directed acyclic graphs that efficiently represent a joint probability distribution over a set of random variables. In the graph, each vertex represents a random variable, and edges represent direct correlations between the variables. Each variable is independent of its non-descendants given the state of its parents. These independencies are then exploited to reduce the number of parameters for characterizing a probability distribution and computing posterior probabilities given the evidence (Stanke and Waack, 2003).

Bayesian networks have been applied to predict the cellular compartment to which a protein will be localized for its function (Bauer *et al.*, 2011). Here, the model integrates protein interactions (PPI), protein domains (Domains), post-translational modification sites (Motifs), and protein sequence data. For each protein, the network receives Boolean inputs of its random variables, e.g., ‘Protein-interacts-with-Pml’=False, ‘Protein-sequence-has-SUMO-site’=True, and ‘Protein-associates-with-PML-bodies’=False, which are processed in its unobserved latent variables, which represent PPI, Domains, and Motifs. The sequence information is provided by a SVM classification over the protein sequence, and presented to the network as an output variable. The

compartment variable itself is hence located between the latent variables and the output variables, and the probabilities are inferred during the training. This has the benefit that the input of the latent variables (the variables with missing data because they are unobserved or missing) is not required to be present for all variables, which makes the resulting network robust against missing information.

Markov networks

Markov networks are also called Markov random fields (MRF) or undirected graphical models, are commonly used in the statistical Machine Learning domain to succinctly model spatial correlations. A Markov random field includes a graph G ; the nodes represent random variables, and the edges define the independence semantics between the random variables. A random variable in a graph, G , is independent of its non-neighbours given the observed values for its neighbours (Krogh, 1997).

Probing cellular networks from different perspectives, using high-throughput genome-wide molecular assays, has become an important study in molecular biology. Probabilistic graphical models represent multivariate joint probability distributions through a product of terms with a few variables. These models are useful tools for extracting meaningful biological information from the resulting data sets (Friedman, 2004).

Hidden Markov Models

The hidden Markov model (HMM) is an important statistical tool for modelling data with sequential correlations in neighbouring samples, such as in time series data. Its most successful application has been in natural language processing (NLP). HMM have been applied with great success to problems such as part-of-speech tagging and noun-phrase chunking (Blunsom, 2004). In HMM, hidden variables are controlling the mechanism of how the data are generated. So, the attributes are directly affected by the hidden variables, for example, a segment of speech is dedicated to pronouncing a syllable, and this syllable can be seen as a value of a hidden variable.

HMMs have been used to resolve various problems of biological sequence analysis (Won *et al.*, 2007), including pairwise and multiple sequence alignment (Durbin *et al.*, 1998; Pachter *et al.*, 2002), base-calling (Liang *et al.*, 2007), gene prediction (Munch and Krogh, 2006), modelling DNA sequencing errors (Lottaz *et al.*, 2003), protein secondary structure prediction (Won *et al.*, 2007), fast ncRNA annotation (Weinberg and Ruzzo, 2006), ncRNA identification (Zhang *et al.*, 2006), ncRNA structural alignment (Yoon and Vaidyanathan, 2008), acceleration of RNA folding and alignment (Harmanci *et al.*, 2007), and many others (Yoon, 2009).

Pair HMMs can be used in dynamic programming (DP) for resolving alignment problems. A pair HMM emits a pairwise alignment in comparison with generalized HMMs (Durbin *et al.*, 1998). A combined approach named generalized pair HMM (GPHMM) has been developed in conjunction with approximate alignments, which allows users to state bounds on possible matches, for a reduction in memory (and computational) requirements, rendering large sequences on the order of hundreds of thousands of base pairs feasible. GPHMMs can be used for cross-species gene finding and have applications to DNA-cDNA and DNA-protein alignment (Pachter *et al.*, 2002).

HMMs have been widely applied for modelling genes. The *ab initio* HMM gene finders for eukaryotes include BRAKER1 (Hoff *et al.*, 2016), Seqping (Chan *et al.*, 2017), and MAKER-P (Campbell *et al.*, 2014). A procedure, GeneMarkS-T (Tang *et al.*, 2015), has been developed to generate a species-specific gene predictor from a set of reliable mRNA sequences and a genome. HMMs have demonstrated that species-specific gene finders are superior to gene finders trained on other species. Acyclic discrete phase-type distributions implemented using an HMM are well suited to model sequence length distributions for all gene structure blocks (Munch and Krogh, 2006). The state structure of each HMM is constructed dynamically from an array of sub-models that include only gene features from the training set. The comparison result from each individual gene predictor on each individual genome has demonstrated that species-specific gene finders are superior to gene finders trained on other species (Munch and Krogh, 2006).

A systematic approach, named EBSeq-HMM, using an HMM has been applied to modelling RNA-seq. In EBSeq-HMM, an auto-regressive HMM is developed to place dependence in gene expression across ordered conditions. This approach has been proved to be useful in identifying differentially expressed genes and in specifying gene-specific expression paths and inference regarding isoform expression (Leng *et al.*, 2015).

The prediction of the secondary structure of proteins is one of the most popular research topics in the bioinformatics community. The tasks of manual design of HMMs are challenging for the above prediction, an automated approach, using Genetic Algorithms (GA) has been developed for evolving the structure of HMMs. In the GA algorithm, the biologically meaningful building blocks of proteins (the set of 20 amino acids) are assembled as populations of HMMs. The space of Block-HMMs is discovered by mutation and crossover operators on 1662 random sequences, which are generated from the evolved HMM. The standard HMM estimation algorithm (the Baum-Welch algorithm) was applied to update model parameters after each step of the GA. This approach uses the grammar (probabilistic modelling) of protein secondary structures and transfers it into the stochastic context-free grammar of an HMM. This approach provides good performance of the probabilistic information on the prediction result under the single-sequence condition (Won *et al.*, 2007).

Non-coding RNAs (ncRNAs) are RNA molecules that are transcribed from DNA but not believed to be translated into proteins (Weinberg and Ruzzo, 2006). The ncRNA sequences play a role in the regulation of gene expression (Zhang *et al.*, 2006). The state-of-art methods, Covariance models (CMs), are an important statistical tool for identifying new members of a ncRNA gene family

in a large genome database using both sequence and RNA secondary structure information. Recent speed improvements through applying filters have been achieved (Weinberg and Ruzzo, 2006). In the development of detection methods for ncRNAs, Zhang *et al.* propose efficient filtering approaches for CMs to identify sequence segments and speed up the detection process. They built up the concept of a filter by designing efficient sequence based filters and provide figures of merit, such as G + C content, that allow comparison between filters. Zhang *et al.* (2006) also designed efficient sequence-based HMM filters to construct a new formulation of the CM that allows speeding up RNA alignment. This approach has been illustrated its efficiency and capability on both synthetic data and real bacterial genomes (Zhang *et al.*, 2006). Because many ncRNAs have secondary structures, an efficient computational method for representing RNA sequences and RNA secondary structure has been proposed for finding the structural alignment of RNAs based on profile context-sensitive hidden Markov models (profile-csHMMs) to identify ncRNA genes. The framework, based on profile-csHMMs, has been demonstrated to be effective for the computational analysis of RNAs and the identification of ncRNA genes (Yoon and Vaidyanathan, 2008).

The accuracy of structural predictions can be improved significantly by joint alignment and secondary structure prediction of two RNA sequences. Applying constraints that reduce computation by restricting the permissible alignments and/or structures further improves accuracy. A new approach has been developed for the purpose of establishing alignment constraints based on the posterior probabilities of nucleotide alignment and insertion. The posterior probabilities of alignment and insertion are computed for all possible pairings of nucleotide positions from the two sequences by a forward-backward calculation using a hidden Markov model. The co-incidence for nucleotide position pairs are obtained from these combined alignments, insertion posterior probabilities and the co-incidence probabilities are thresholded by a suitable alignment constraint, and this constraint is integrated with a free energy minimization algorithm for joint alignment and secondary structure prediction (Harmanci *et al.*, 2007).

A prediction method for a transcription factor prediction database has been implemented using profile HMMs of domains, and used for identifying sequence-specific DNA-binding transcription factors through sequence similarity. Transcription factor prediction based on HMMs of DNA-binding domains provides advantages. It is more sensitive than conventional genome annotation procedures because it uses the efficient multiple sequence comparison method of HMMs, and it recognizes only transcription factors that use the mechanism of sequence-specific DNA binding (Kummerfeld and Teichmann, 2006).

Deep Learning

Deep learning provides computational models composed of multiple processing layers to learn representations of data with multiple levels of abstraction. These approaches have significantly improved the state-of-the-art in speech recognition, visual object recognition, and many other domains including biology, such as drug discovery and genomics. Deep learning has identified complex structures in large datasets by using the backpropagation algorithm. Backpropagation is an approach applied to estimate the error contribution of each neuron after the training data is processed. This algorithm can guide the network to change its internal parameters, to determine the representation in each layer from the representation in the previous layer (Lecun *et al.*, 2015).

As mentioned earlier, a standard neural network (NN) includes many simple, connected processors called neurons, each generating a sequence of real-valued activations. The input neurons become activated through sensors perceiving the environment, other neurons become activated through weighted connections from previously active neurons (Schmidhuber, 2015). However, simply stacking many layers of neurons together, i.e., making the model “deep”, will not increase model performance in accuracy by much. There is a need for an effective training algorithm in deep structures. In the late 1990s, there were some attempts to alleviate this problem. The convolutional neural network (CNN) (Lecun *et al.*, 1998) was proposed in 1998 in which parameter sharing and sparsity were introduced and implemented as convolutional operations in layers close to the input layer. Despite its outstanding performance, it was largely ignored. In 2006, the Restricted Boltzman Machine (RBM) was introduced (Hinton *et al.*, 2006) where neurons are treated as probabilistic units defined by energy functions (similar to a Markov Random Field). It was trained layer by layer. This provided a practical tool to make the networks really deep, i.e., containing many layers, and therefore representing very complex models with a large number of parameters to tune.

Meanwhile, computational platforms moved from vertical scaling to horizontal scaling, leading to fast growth in parallel computing and the emergence of GPUs (general computing units). These new platforms made the training of large-scale networks possible, which, in turn, stimulated the growth of deep learning. Many very deep CNNs were proposed and successfully applied to computer vision problems. Furthermore, many other neural networks designed for temporal data such as speech went deep as well, resulting in deep recurrent neural networks (DRNN) where connections between units form a directed cycle. A particular form of RNNs called long short-term memory (LSTM) was very successful in natural language processing. Now deep learning models are incorporating other learning techniques, such as reinforcement learning (Van Otterlo and Wiering, 2012), which combines learning and generative models to solve complex problems such as game playing (AlphaGo), and design (Autodesk generative design), to name a few. Reinforcement learning is a field of machine learning inspired by behaviourist psychology. Reinforcement learning is the problem that an agent resolves it by learning behaviour through trial-and-error interactions with a dynamic environment (Kaelbling *et al.*, 1996).

Deep learning requires a large amount of data for the training process. However, this can be alleviated by adopting some transfer learning techniques, i.e., localizing pre-trained models, which have been trained on readily available related data sets, and then fine-tuned on higher quality data.

Deep learning has been used in omics, biomedical imaging, and biomedical signal processing for bioinformatics (Min *et al.*, 2016). The generation of different transcripts from single genes is guided by the alternative splicing (AS) process. A model has been implemented using a deep neural network, trained on mouse RNA-Seq data, that can predict splicing patterns in individual tissues, and differences in splicing patterns across tissues. Their framework uses hidden variables jointly representing features in genomic sequences and tissue types for predictions (Leung *et al.*, 2014). In biomedical imaging research, deep learning approaches have been demonstrated to have the capability to learn physiologically important representations, such as independent component analysis (ICA) and restricted Boltzmann machine (RBM), and detect latent relations in neuroimaging data (Plis *et al.*, 2014). Buggenthin *et al.* present a deep neural network that predicts lineage choice in differentiating primary hematopoietic progenitors using millions of image patches from brightfield microscopy and cellular movement. They combine a CNN with an RNN architecture to automatically detect local image features and retrieve temporal information about the single-cell trajectories. This approach provides a solution for the identification of cells with differentially-expressed lineage-specific genes without molecular labelling (Buggenthin *et al.*, 2017). In biomedical signal processing research, brain signals have been decoded with Deep Belief Networks, probabilistic generative models that are composed of multiple layers of latent variables, and identified higher correlations with neural patterns than Principal Component Analysis (PCA).

Conclusion

Here we have provided an overview of different Machine Learning technologies and their application in the bioinformatics space. As also covered by Libbrecht and Noble, the choice of methodology depends on the properties of the available data as well as the intended outcome (Libbrecht and Noble, 2015).

We have covered supervised versus unsupervised learning, exemplified by FFNN and K-means methods respectively. The supervised FFNN approach has been used for designing novel proteins with site-directed recombination (Bauer *et al.*, 2006), where the Machine Learning models could learn from annotated examples. In contrast, the unsupervised K-means clustering in VariantSpark groups patients based on their genomic profile, which for a global population represents the different ethnicity groups (O'Brien *et al.*, 2015).

We also gave examples of choosing methodologies to achieve specific outcomes. For example we used a SVM for SUMOylation site prediction in protein sequence, as the intent was to develop the most accurate predictor (Bauer *et al.*, 2010). The trade-off for excellent performance here was the lack of insight into which biological feature contributes to the outcome. However, if gaining insights is the intent, as it was for the CRISPR target site prediction (Wilson *et al.*, CRISPR Journal accepted), then a methodology such as RF, is more advisable as it provides a feature-importance score after training.

Throughout the article we referred to "Big Data", which is particularly attractive for Machine Learning. This is because Machine Learning relies on the iterative process of learning from examples, which requires data to be kept close to the compute resources, and ideally in memory. Recent developments in the distributed computing space have enabled this in a standardized framework, namely Apache Hadoop, and for better memory management, Apache Spark.

We therefore also discussed VariantSpark, a Machine Learning framework for high-dimensional complex data, such as genomic information (O'Brien *et al.*, 2018). It offers supervised and unsupervised Machine Learning methods, and specifically its RF implementation exceeds other Spark-based parallelization attempts in the volume of data, e.g., Google's Plant implementation (Panda *et al.*, 2009). As such, it can be applied to datasets with millions of features to fit multi-variate models, e.g., to perform Genome wide association studies (GWAS) capturing the complex interaction between genomic loci.

In conclusion, the Machine Learning field is an exciting and rapidly evolving space especially in life sciences, as data volumes here will outpace those of traditional Big Data disciplines, like astronomy or retail. Hence, dramatic breakthroughs in advanced Machine Learning or Artificial Intelligence can be expected from this domain over the next years.

Biographical Sketch

Dr. Kaitao Lai is a postdoctoral fellow at the Transformational Bioinformatics Team in Australian eHealth Research Centre and CSIRO Health and Biosecurity Business Unit. His expertise is in genome informatics, high throughput genomic data analysis, computational genome engineering, genome editing, as well as big data analysis and elastic cloud computing. He received his PhD in Bioinformatics for Plant Biotechnology and worked on microbial genomic and metagenomics data analysis, pan-genome analysis in previous postdoctoral fellow position. He is currently working on the development of predictors for CRISPR-Cpf1 in genome editing by training a Random Forests (RF) Machine Learning method, and facilitating the adaptation of the latest developments in computing infrastructure (e.g., Spark for big data analytics) and cloud technology (e.g., AWS Lambda) for research projects and commercial software products.

Dr. Natalie A Twine is a postdoctoral fellow at the Transformational Bioinformatics Team in Australian eHealth Research Centre and CSIRO Health and Biosecurity Business Unit. She works with big data technologies to understand the genetic basis of ALS. This is a collaborative project with Macquarie University and the international consortium, Project MinE. Dr. Twine has expertise in high throughput genomic and transcriptomic data analysis, clinical genomics, genetics and big data analysis. She obtained her PhD in Bioinformatics from University of New South Wales and has previously worked at UNSW, Kings College London and University College London. Natalie has 19 peer-reviewed publications (6 as senior author) with 835 citations and h-index of 12.

Aidan O'Brien is a joint PhD student between CSIRO and the John Curtin School of Medical Research at the Australian National University. His PhD project is aimed at developing sophisticated Machine Learning models to facilitate accurate CRISPR knock-in applications. He is working together with Australia's premier CRISPR facility to validate his models on novel datasets and enable new application areas. He graduated from the University of Queensland with a Bachelor of Biotechnology (1st class honours) in 2013. In his previous work, he developed GT-Scan and VariantSpark. Aidan has 4 journal publications (3 first author) with 61 citations (h-index 3). He received the "Best student and postdoc" award at CSIRO in 2015 and attracted \$180K in funding to date as AI.

Dr. Yi Guo received the B. Eng. (Hons.) in instrumentation from the North China University of Technology in 1998, and the M. Eng. in automatic control from Central South University in 2002. From 2005, he studied Computer Science at the University of New England, Armidale, Australia, focusing on dimensionality reduction for structured data with no vectorial representation. He received a PhD degree in 2008. From 2008 until 2016, he was with CSIRO, working as a computational statistician on various projects in spectroscopy, remote sensing and materials science. He joined the Centre for Research in Mathematics, Western Sydney University in 2016. His recent research interests include Machine Learning, computational statistics and big data.

Dr. Denis Bauer is the team leader of the transformational bioinformatics team in CSIRO's ehealth program. She has a PhD in Bioinformatics from the University of Queensland and held Post-doctoral appointments in biological Machine Learning at the Institute for Molecular Bioscience and in genetics at the Queensland Brain institute. Her expertise is in computational genome engineering and BigData compute systems. She is involved in national and international initiatives tasked to include genomic information into medical practice, funded with \$200M. She has 31 peer-reviewed publications (14 as first or senior author) with 7 in journals of IF > 8 (e.g., Nat Genet.) and H-index 12. To date she has attracted more than \$6.5 Million in funding as Chief investigator.

Artificial Intelligence

Francesco Scarcello, University of Calabria, Rende, Italy

Introduction

Capturing the intrinsic nature of intelligence is one of the most fascinating questions in the history of humankind. Providing machines with its essence is one of the most fascinating ambitions in computer science.

The term Artificial Intelligence (or, simply, AI) was first used in 1956 by John McCarthy, one of the fathers of this field, to name a research conference. It is however intimately connected with logic, reasoning, cognitive science, and philosophy, so that in a sense it started with the Greek philosophers and has never stopped.

Alan Turing was probably the first to deal with the possibility of adding reasoning capability to machines, and to try to formalize the extent to which this may be possible. His paper “Computing Machinery and Intelligence” (Turing, 1950) begins with the following famous sentence: “I propose to consider the question: Can machines think?”. Instead of getting stuck in defining what we mean by an intelligent machine, he proposed a sort of imitation game, universally known as the Turing test, to identify such an “intelligent machine”. Roughly, the test is passed by a machine player if a human interrogator is not able to distinguish such an “artificial” player from human players, by putting questions (in natural language) to them. By 1966, the famous software “Eliza” performed well in the Turing test by just responding to the user’s sentences with either a generic reply or by repeating, in a slightly modified form, previous comments of the user. More recently, a similar (but malware) program called “CyberLover”, sought relationships on the Internet in order to steal personal data. Clearly enough, such programs are quite far from human intelligence, nevertheless the Turing test has been an important stimulus for developing machines exhibiting intelligent features.

Together with the contribution of many other researchers such as Gödel, Church, Karp, and Cook, just to name a few, Turing pointed out what can be computed and what cannot be computed by algorithmic procedures. In particular, since the 1970’s, it has been known that most forms of reasoning that are common to humans lead to problems that cannot be solved by our computers within an acceptable amount of time and with reasonable memory resources (unless some unlikely collapse occurs in complexity theory). Is it thus impossible for a machine to perform tasks where intelligence is needed? This classic question implicitly contains two further crucial questions: Which machine? Which intelligence? We know that there are different forms of (human) intelligence as well as different possible kinds of machines, such as quantum computers or biological machines, and new ones may come out in a not-so-distant future.

Anyway, even if no machine exhibits all facets of human intelligence, we now have machines that excellently perform many tasks previously possible only for (intelligent) humans, such as playing Chess or Go, and driving cars. Machines are starting to exhibit the ability to learn, which is a fundamental feature of intelligence. They have learned to recognize objects and faces, to process natural language sentences, and to perform many other difficult tasks. The availability of huge amounts of data that can be used for training such learning machines has led to an explosion of AI applications.

AI is becoming ubiquitous and it is going to support every human activity, from communication to healthcare, from business to entertaining. This paves the way for new questions about the ethics of AI and its impact on the economy, on the future of work, and on society, in general.

The rest of this contribution provides perspectives to some of the main facets of Artificial Intelligence. Each section below focuses on one facet, but recall that they are all part of the same puzzle, and their correlation is continuously increasing over the years.

Knowledge Representation, Reasoning, and Logic

Since the early days of AI, a crucial question has centered on how to move from raw data to information and knowledge. Indeed, *knowledge* is a precious resource that humans often keep implicitly somewhere in their brain. It is quite difficult to represent even the simple knowledge of a child, and consequently to perform basic human-like reasoning tasks, also known as commonsense reasoning (Van Harmelen *et al.*, 2008).

How can we formalize the semantics of data in a way that can be managed by machines? We next give a short overview.

Logic and Non-Monotonic Reasoning

The first approaches to knowledge representation were based on logic, starting from the ability of predicate calculus to state facts about the world, as well as to provide tools for reasoning about these facts. For instance, consider a fragment of a knowledge base (KB) encoding personal data about the inhabitants of some city. We may say

male(francesco). male(mario). female(alessia). female(sara).

$\forall x. \text{person}(x) \leftarrow (\text{male}(x) \vee \text{female}(x))$

The first line contains a list of facts representing extensional knowledge about the citizens. The first-order logic sentence in the second line encodes a form of intentional knowledge: the predicate *person* is represented by means of its logical connection to *male* and *female*, without explicitly listing who are all persons in the world. According to the *Closed World Assumption* (quite common in logic-based KBs), the extensional knowledge is considered complete. That is, in the above example, every instance of *male(X)* that does not occur as a fact in the KB is considered “false”.

By means of logical formulae we automatically infer new knowledge, and logic can be used for reasoning, too. It is crucial for an AI machine to perform *non-monotonic reasoning*, where, unlike classical logic, the addition of new knowledge may invalidate previous beliefs. Indeed, we are used to dealing with exceptions, to deducing, by default, conclusions that can be later invalidated, to defining theories that best explain a certain set of observations, and so on. For instance, most semantics for KBs are based on the so-called *negation-as-failure* concept, which says that we believe to be “false” every predicate that cannot be proved to be “true”. In the citizens example, we can infer that “*not person(pippo)*” is “true”, because both *male(pippo)* and *female(pippo)* cannot be proved to be true, which entails that, given the current knowledge, *person(pippo)* cannot be proved to be true, too. Further notable examples of non-monotonic frameworks in the huge AI literature include Default Reasoning, Circumscription, Abduction, Autoepistemic logics, and Belief Revision (Brewka, 1991).

In some contexts, it is useful to represent different modalities of qualifying facts and sentences. For example, for a given statement *p*, we may want to say that “*p* is possible”, or “*p* is necessary” (that is, “it is not possible that *p* does not hold”), or “*p* usually holds”, and so on. Modal logics provide a formal approach to representing this form of knowledge, and for reasoning on it. There are many modal logics, based on different modal operators and semantics. In particular, there are also temporal modal operators to represent statements such as “eventually *p* holds”, or “it has always been that *p*”, and so on (Blackburn et al., 2006).

Starting from knowledge of mathematical axioms, we can perform *Automated Theorem Proving*, see, e.g., (Gallier, 2015; Fitting, 2012) for an introduction to the subject.

Logic Programming

It turned out quite soon that logic could be used for quite general tasks, and the logic programming framework came out (Lloyd, 2012). One of the most important and widely known logic programming languages is Prolog (Sterling and Shapiro, 1994), which was initially developed for natural language processing, and later used for building expert systems, automated planning, and so on. The idea at the heart of logic programming is that problems can be solved automatically, if they are properly formalized in a logical way. Therefore, in contrast with the imperative paradigm of classical machine-oriented programming languages (think of C, Pascal, and the like), Prolog aims at a declarative approach where the user writes down a set of logical facts and rules encoding the problem at hand, and the system does the rest.

However, the semantic of Prolog is not fully declarative, so that further logic-based languages equipped with declarative semantics have been developed. See (Dantsin et al., 2001) for a study of the complexity and the expressive power of logic programming. In order to perform advanced queries to database management systems in a declarative way, the Datalog language has been proposed (Gottlob et al., 1990). Besides negation-as-failure, recently the core language has been extended with further powerful constructs, giving rise to so-called Answer-set Programming (ASP). Knowledge-base systems based on ASP have been implemented and engineered, and are currently used worldwide both for research and in commercial applications (Leone et al., 2006; Kaufmann et al., 2016).

Class-Based Representations and Description Logics

Another approach to knowledge representation in AI is based on network structures that encode individuals and their relationships. Starting with the notions of semantic networks (Lehmann, 1992) and frame systems (Fikes and Kehler, 1985), this line of research is currently best represented by Description Logics (DLs), see, e.g., (Baader, 2003). Contrasted with Datalog and its extensions, the domain of DLs is not finite, in general, and the closed-world assumption does not hold. That is, the individuals explicitly listed in the knowledge base are not necessarily all the relevant individuals in the world. DLs are useful for reasoning with ontologies and provide a powerful logical formalism for the Semantic Web. The standard Ontology Web Language (OWL), defined by the World Wide Web Consortium (W3C) Web Ontology Working Group, is, indeed, based on a DL (Horrocks, 2008). In particular, DLs (and OWL) find applications in knowledge representation in Bioinformatics, e.g., for terminology databases such as SNOMED CT, GALEN, and GO.

Rational Agents

In the age of the Internet of Things, where every device, even the smallest one, is programmable and equipped with some sort of intelligence, AI must deal not only with the intelligence of single machines but with the intelligence of many agents interacting with each other. Agents may be machines, humans, or a hybrid combination, and typically agents have contrasting preferences and goals.

Let us first consider the case of agents with a common goal, which cannot be reached by means of a classical central algorithm. Think for instance of sensor networks or other networks comprising cheap devices with limited sensing, processing, and communication capabilities. For these applications, distributed constraint satisfaction algorithms have been proposed in the literature (Faltings, 2006). Actually, in most cases, we would like to compute a best solution rather than any solution that meets the given

constraints, and we would like to get it from the agents in a distributed way. This is the case, e.g., of path-planning problems and of many economic applications involving weighted matching and scheduling problems (Yokoo, 2012).

Strategic Agents

Quite often, agents have diverging goals and preferences. *Game Theory* provides mathematical models and tools for studying both the case where the agents are selfish and play in a strategic way, and the case where agents are cooperative and form coalitions to obtain their best outcome (Von Neumann and Morgenstern, 1944; Osborne and Rubinstein, 1994).

In the former case, a classical result states that there always exists at least a vector of choices of all players (combined strategy) such that no player may increase her payoff by deviating from it (Nash, 1950). Such a vector is called Nash equilibrium, after the Nobel prize winner J.F. Nash, who defined it. However, its existence is guaranteed only holds if agents' choices are given in terms of probability distributions (called mixed strategies), rather than precise deterministic choices (called pure strategies). This paves the way for many "philosophical" interpretations of this result, as well as to connections among mixed strategies and the collective behavior of populations of living creatures in their quest for survival (Weibull, 1997).

Computing Nash equilibria is quite difficult from a computational point of view, as it is PPAD-complete for two-player games (Chen and Deng, 2006), as well as for multi-player games represented in a succinct way (Daskalakis et al., 2006). In the latter case, when pure strategies are considered, deciding the existence of a Nash equilibrium is an NP-complete problem (Gottlob et al., 2005).

In many cases, agents do not interact in a one-shot manner, and games consist of repeated turns. Then, the notions of strategies and of best responses do change, and any agent has the opportunity to modify her way of playing on the fly, depending of what the other players are doing. Moreover, often there is uncertainty about the knowledge of other agents' preferences, so that their actual moves in a repeated game provide precious information (we say the game does not have perfect knowledge).

Many algorithms for computing Nash equilibria, as well as variants of these equilibria, have been developed. We mention the library of tools called GAMBIT (McKelvey et al., 2006), and the suite for generating games and evaluating algorithms called GAMUT (Nudelman et al., 2004).

There are two-player games that end with a winner and a loser, think of chess or checkers. More generally, in a multiplayer game, agents may have opposite goals so that their possible outcomes always sum to zero. However, this is not always the case, and there are many situations where the agents can reach a best outcome by collaborating with each other. An important question is thus whether or not selfish agents looking for their personal highest profits are able to precisely choose those strategies that lead to the best (or at least a good) global outcome. A measure of the worst-case distance between any equilibrium and a desirable one is known as the *price of anarchy* (Koutsoupias and Papadimitriou, 1999).

The question is particularly interesting in repeated games, where a rational agent may learn from what happens in any turn of the game (Crandall and Goodrich, 2011). In particular, in repeated games, the necessity of cooperating with other rational agents to improve the overall performance may emerge as a prominent behavior. Recent experiments show that, from this point of view, machines seem to be better than human agents in learning to cooperate in repeated games, and they are also good at cooperating with humans (Crandall et al., 2017).

Coalitional Games

Another important field of AI and Game Theory focuses on Coalitional Games (von Neumann and Morgenstern, 1944), which were introduced as tools to reason about scenarios where players work together by forming coalitions, with the aim of obtaining a higher global worth than they would by acting in isolation. In contrast with the strategic games described above, a coalitional game is defined as a pair (N, v) where N is the set of agents and v is a function assigning a worth, $v(C)$, to any possible coalition of agents, C (while in strategic games values are assigned to combined strategies chosen by agents). Coalitional games find applications in voting systems, social choice, communication networks, and auctions, just to name a few.

A crucial problem in coalitional games is to find a way to distribute the total available wellness $v(N)$ to the agents in a way that is perceived as fair. A vector of values assigned to players is called an *imputation* if the available wellness is precisely distributed (efficiency), and if each agent gets at least what she would get by playing alone (individual rationality). Moreover, it is often required that such an imputation is stable, in that no subset of agents have an incentive to leave the group and play on their own (we say that the distribution belongs to the *Core* of the game). Many solution concepts have been defined in the literature to capture different notions of *fairness*, depending on the applications. Notable examples of solution concepts are the Shapley value and the Nucleolus, defined by the Nobel prize winners L.S. Shapley and R.J. Aumann, respectively. For any agent, i , her Shapley value is obtained as a weighted average of her marginal contributions, $v(C) - v(C \setminus \{i\})$, to every possible coalition, C , she may join. The Nucleolus minimizes the dissatisfaction of the coalitions as much as possible. Interestingly, some of these advanced notions of fair division have been known for thousands of years: it has been shown that the 2000-year old Babylonian Talmud describes a (unique) solution for the contested amount in bankruptcy problems that is precisely the nucleolus of a coalitional game that models the problem (Aumann and Maschler, 1985).

In Artificial Intelligence applications, the function v , which assigns a worth to each coalition, is usually represented in an implicit succinct way, for instance in terms of matching of weighted graphs, spanning trees, logical formalisms, and so on. Indeed,

whenever many agents are involved in the game, listing all entries of the worth function would be practically infeasible. The computational complexity of computing solutions for succinct games with non-fixed numbers of agents is intractable, in general (Deng and Papadimitriou, 1994; Greco *et al.*, 2009, 2015). However, there are many important classes of such games that can be dealt with in polynomial time.

For those games where cooperating with all participants is not necessarily the best option, agents may form a number of separate coalitions. This raises further problems about the structure of such coalitions, their stability, and their properties, in terms of solution concepts (Greenberg, 1994).

Mechanism Design

A dual aspect of dealing with autonomous rational agents is to design the rules of protocols for interacting agents, in such a way that some global goals of an external party (the designer) can be met (Nisan *et al.*, 2007). Agents are selfish and try to obtain their best outcome by playing in a strategic way, moreover their actual preferences are usually unknown. Therefore, the challenge in mechanism design is defining the rules of a game so that the desired properties are fulfilled at the end of the game, without having this precious information about the agents. It must be convenient for the agents to play as we would like them do. In particular, one of the basic properties of a mechanism is to make it convenient for agents to be *truthful*, that is, to reveal their actual preferences.

A typical application of mechanism design is in the field of *auctions*, where a given set of goods have to be allocated to selfish agents, who have hidden preferences on how much they value each good. Auctions currently occur everywhere, think for instance of the e-commerce websites, of the process of sharing computational power in a computing grid, and so on. In many cases, auctions on the Internet involve machines as bidders, rather than humans, or machines and humans are mixed.

Mechanism Design provides a general and powerful solution for dealing with such problems. For instance, consider the second-price bid-auction, where some good is to be sold and an agent wins the auction if she bids more than the other players, but she then pays the second highest-price to get the desired good. It turns out that this mechanism is truthful, that is, the strategy where every agent bids according to her actual private valuation of the good dominates all other strategies (Krishna, 2002).

Planning Agents

Consider an artificially intelligent machine consisting of a robot with a number of sensors that measure speed, position and so on. Assume that the robot has the ability to move itself, and possibly other objects in the space, and that it has some goal to achieve.

Such agents are typically implemented using the so-called triple-tower architecture, which comprises the following modules: the perception tower that receives the sensory signals; the model tower that manages knowledge and performs reasoning tasks; and the Action Tower that deals with actuators. In particular, by looking at the current status of the world, the model tower is in charge of defining a *plan*, that is, a sequence of actions allowing the robot to reach the desired goal.

Many planning algorithms have been described in AI literature to identify such action sequences. Some of them are based on logic and on the “Situation calculus”, which provides a predicate-calculus framework to represent states and actions, and to reason about the effects of actions on states. For instance, the language GOLOG, based on it, is used in robotics research (Levesque *et al.*, 1997).

A different and widely used approach to automated planning is based on the STRIPS action language, whose name comes from the very famous Stanford Research Institute Problem Solver (STRIPS) planner (Fikes and Nilsson, 1971).

Constraint Satisfaction

Most algorithms for AI problems search for solutions that range over huge search spaces and that are required to meet a large number of constraints. Sometimes these constraints are very mandatory constraints, and sometimes they just express preferences that we should try to satisfy, as much as possible (soft constraints).

Therefore, an important field of research in AI focuses on constraint satisfaction and constraint processing, and provides many algorithmic tools and theoretical results that are useful in many AI fields. In particular, algorithms for consistency enforcing and constraint propagation, combinatorial and stochastic search strategies, optimization tools for soft constraints, and other kinds of frameworks dealing with preferences (Dechter, 2003).

In general, solving a constraint satisfaction problem (CSP) is computationally intractable, to be precise NP-hard. However, a number of islands of tractability have been identified, that is classes of CSPs that can be solved in polynomial time. Such classes are mainly characterized either by restricting the languages used for defining the constraints (Jeavons *et al.*, 1997; Bulatov, 2013; Carbonnel and Cooper, 2015), or by restricting the (hyper)graph structure representing the way constraints interact with each other (Dechter and Pearl, 1989; Gottlob *et al.*, 2000, 2016; Greco and Scarcello, 2017).

For more information on the subject, see (Rossi *et al.*, 2006).

Machine Learning

The ability to learn is a fundamental feature of intelligent systems. It is becoming ubiquitous in AI applications, and it is at the heart of most of the recent impressive achievements of Artificial Intelligence, such as driving cars, playing chess, recognizing images and persons, and assisting humans in many tasks.

Machine learning started with the same flavor, as we have seen in the first section. That is, the original goal was learning knowledge encoded in some rule-based representation or in terms of decision trees, with a strong connection to cognitive science. A different line of research is based on tools from pattern recognition and statistics, whose outputs use simpler representations, based on attribute-value pairs or propositional representations (Michalski *et al.*, 2013). Another approach to learning by using logic, called Inductive Logic Programming, is based on the inference of logic programs from a given set of positive and negative facts about the subject to be learned (Nienhuys-Cheng and De Wolf, 1997; De Raedt *et al.*, 2008).

Many recent successful applications are based on neural networks, that is, networks of simple computational elements, inspired by the behavior of the neurons in the brain, and proposed since the early days of AI. Basically, the artificial neurons are arranged in layers and are connected through digital synapses. The bottom layer is in charge to processing the input signals; then, each neuron in a layer integrates, according to some (simple) function, the values received through its synapses in a new value, and propagates it to the next layer. The parameters of the functions acting at each neuron are repeatedly modified during the training process, depending on the network response to positive and negative examples of the subject to be learned.

There are now powerful tools, some are even open source (e.g., TensorFlow, originally developed by the Google Brain Team), that allow researchers and practitioners to easily develop powerful learning systems. From the uncountable successes of such technology, consider, for example, the AlphaGo software developed for playing Go by DeepMind. This is a nice example of AI software because it combines machine learning with randomized searches on trees. The deep learning part uses two neural networks, the value network and the policy network. The first training was performed using a database of 30 million moves from classical matches. Then, the algorithm continued to learn by playing against other AlphaGo machines.

A drawback of deep learning techniques lies in the so-called “black box problem”: unlike the alternative symbolic approach to learning, here the knowledge is hidden in the network parameters and we are not able to understand precisely what happens there and why. As a consequence, if something goes wrong it is not clear how to deal with the problem. There are experiments that show quite trivial cases that are misunderstood by the network, with no easy fix (Castelvecchi, 2016).

Natural Language Processing

Providing machines with the ability to communicate by written and spoken natural languages is one the first and most widely studied objectives in AI and computational linguistics. Recent advances in recognizing the human voice and in processing its features, allows us to use our voice and natural language for human-to-machine communications, such as asking questions to online and even mobile phone assistants, controlling cars or robots, and so on (Jurafsky and Martin, 2000).

In fact, natural language processing (NLP) does even more. By using real-time translation tools, we use NLP to communicate with other humans from different countries, by simply talking to a mobile phone and letting it pronounce, in a different (natural) language, what we have said. Eventually, in a similar way, we will also use NLP for communicating with different kinds of machines. In fact, large real-world organizations typically use many knowledge bases (KBs), encoded in different ways, and equipped with different querying and reasoning languages. Therefore, in practice, these KBs are not able to operate in a combined way, unless the organization invests (much) time and money in providing auxiliary tools for integrating them. NLP may be the key to leveraging such heterogeneous KBs by providing a common and highly accessible interface.

NLP is also used for sentiment analysis, that is, for detecting subjective information from documents, social networks, and so on. It is useful for identifying trends in users’ opinions that can be exploited, e.g., for marketing purposes or for politics.

NLP systems are quite complex and comprise many different tasks, whose implementation often relies on statistical and machine learning tools (Goldberg, 2016). These tasks include: *Syntactical tasks*, such as translating a natural language sentence to a representation in some formal grammar, by performing lemmatization, tagging the different parts of speech, and then parsing the resulting objects in order to identify the roles of words in the sentence and their relationships. *Semantical tasks*: moving from syntax to meaning by disambiguating words, performing entity recognition (by identifying proper names of persons and places, as well as their types), and identifying possible semantic relationships among these entities. *Discourse processing*: analyzing the structure of a discourse, determining which words refer to the same entities, and possibly producing automatic summaries. *Speech recognition*: determining a textual representation of a human speech by performing speech segmentation and recognizing allophones and phonemes in speech sounds.

Biographical Sketch

Francesco Scarcello received the Ph.D. degree in Computer Science from the University of Calabria in 1997. He is a full professor of computer science (SSD ING-INF/05) at the University of Calabria, and he serves as an Associated Editor for the journal *Artificial Intelligence*, edited by Elsevier. His research interests are computational complexity, game theory, (hyper)graph theory, constraint satisfaction, logic programming, knowledge representation, non-monotonic reasoning, and database theory. He has extensively published in all these areas in leading conferences and journals. His paper "Pure Nash Equilibria: Hard and Easy Games" received the 2008 IJCAI-JAIR Best Paper Prize, awarded to an outstanding paper published in the Journal of Artificial Intelligence Research in the preceding five years. His paper "Hypertree Decompositions and Tractable Queries" received the 2009 ACM PODS Alberto O. Mendelzon Test-of-Time Award, awarded every year to a paper published in the proceedings of the ACM Symposium on Principles of Database Systems (PODS) ten years prior that had the most impact in terms of research, methodology, or transfer to practice over the intervening decade. In 2016, his paper "Hypertree Decompositions: Questions and Answers" was invited for the special *Gems of PODS* session, at the 35th ACM Symposium on Principles of Database Systems.

Introduction

Knowledge representation and reasoning (KR&R) is one of the foundations of Artificial Intelligence (AI). In particular, the key role of KR&R for AI relies on the hypothesis that symbolic reasoning coupled with explicit representations of knowledge may provide computers with the ability to algorithmically solve complex real world problems. In particular, the idea is to equip computer programs with a formal representation of problem domains (called *knowledge representation*) coupled with logical inference techniques in order to solve complex problems mimicking natural *reasoning*.

Former approaches for knowledge representation (KR) date before the advent of the computer era. However, they were mainly developed by mathematical logicians, who disregarded nonmathematical knowledge representation. Nonetheless, classical mathematical logic significantly influenced KR research. First-order (predicate) formulas form the basis of classical logic and declarative knowledge representation (McCarthy, 1958; Robinson, 1965). Transitive closure and related relevant concepts, however, revealed to be crucial in KR but needed more expressive formalisms; these have been introduced with the formalization of second-order formulas, which paved the way to modern logic. Some non “classical” approaches to knowledge representation introduce belief in their syntax (Gettier, 1963; Hintikka, 1962) or non classical semantics, like intuitionistic logic or super-intuitionistic logic of strong equivalence (Goble, 2001); these will not be considered in this article.

Several proposals exist among modern methods for knowledge representation and reasoning. In particular, Description Logics (DL) (Baader *et al.*, 2003; Franz and Sattler, 2001; Calvanese *et al.*, 2001) are a family of KR languages based on logic, where concept *descriptions* constitute the key ingredient. Descriptions are obtained from atomic concepts (unary predicates) and atomic roles (binary predicates). DLs are equipped with a formal, logic-based, semantics. They are currently the core representation languages for the Semantic Web and in particular for ontology representations.

Constraint programming (Apt, 2003; Frühwirth and Abdennadher, 2003; Hentenryck and Michel, 2005) is another powerful paradigm particularly suited for solving combinatorial search problems. It combines a wide range of techniques from artificial intelligence, operations research, algorithms and graph theory. In this case, the problem of interest must be expressed as a constraint satisfaction problem (CSP), where constraints are relations and the solution states which relations should hold among the given variables. General purpose constraint solvers can be used to get CSP, and consequently problem, solutions. However, expressing a generic problem in terms of constraints might be not obvious.

SAT solvers (Kautz and Selman, 2007) are based on propositional logic, and provide a framework for generic combinatorial reasoning. They are tailored to solve SAT formulas, but their full potential is evident when problems not directly encoded in propositional logics are expressed as boolean satisfiability, such as planning and verification problems. In fact, an increasing amount of practical applications can be solved with surprising efficiency by modern SAT solvers; as a matter of facts, they are able to solve hard problems with more than a million variables and several million constraints. Also in this case, one of the key issues is the proper reduction of the problem into a SAT formula.

Conceptual graphs (Michel and Mugnier, 2009) provide an expressive language and powerful reasoning capabilities; they provide a graph representation for logic, based on semantic networks. The main application domain of conceptual graphs is Natural Language Processing. Several extensions have been proposed for this model, such as contexts, metalanguage, plural nouns, etc.

In the context of declarative languages, one of the former languages proposed in the literature has been Prolog, developed since late 1970s. Here, knowledge is represented by clauses (specifically by definite clauses) and reasoning is carried out by the SLD resolution inference method. Solving a problem in this context, reduces to determining whether objects in the domain satisfy given properties or not. Prolog provides an easy way of representing knowledge and is endowed with efficient implementations. However, the language is not completely declarative and presents some issues related to the interpretation of the programs. As a matter of facts, it may happen that, given two slightly different variants of the same program, being completely equivalent from a declarative point of view, one of them solves the problem, whereas the other one goes into an infinite loop.

A less expressive, but fully declarative, knowledge representation language that emerged along Prolog is Datalog. In this context, the declarative language is used for a formal representation of the knowledge about the problem of interest and the result is a logic program. Queries to the program, then, define the reasoning. Results of the reasoning are eventually computed by an inference engine applied to the query and the program. It is important to point out that the combination of Datalog with an inference engine can provide answers to very hard problems in NP and beyond. As a consequence, if on the one hand Datalog is a subset of Prolog, on the other hand it significantly extends traditional query languages for relational databases. This is one of the reasons why Datalog showed up to be a particularly good candidate for practical applications.

Limitations of Datalog in terms of expressiveness have been addressed by Answer Set Programming (ASP). ASP is a declarative language for KR&R based on the Answer Set Semantics (Zbigniew and Truszczyński, 2006; Niemelä, 1999). It is influenced by former declarative programming languages, but also by database languages. Instead of providing a full general-purpose language for KR&R, it focuses on relevant language requirements for real-world applications. It includes nonmonotonic reasoning,

incomplete knowledge, hypothetical reasoning and default assumptions. ASP emerged in the logic programming context as one of the most influential tools for KR&R even in industrial applications, coupled with highly engineered ASP evaluation engines which are continuously improved and updated. As a matter of facts, thanks to the introduction of nonmonotonic reasoning, ASP can express all problems in the complexity class $(\Sigma)_2^P$ and its complement Π_2^P . The important role of ASP in the bioinformatics context has been recently evidenced in, (Erdem *et al.*, 2016) where several bioinformatics problem solutions based on ASP are reviewed.

Since the literature on KR&R is so vast, and since ASP emerged as a success story for the application of KR&R to bioinformatics, in the rest of this article we will focus on this formalism.

Background

In ASP, knowledge representation is based on rules, which are interpreted according to common sense principles. A program is, then, a collection of rules which represents a problem to be solved. This program, together with some input, may have several (but even none) solutions. Solutions to the program are then solutions to the problem. As for Datalog, solutions to the program are determined by an inference engine. In what follows, we provide an overview of the core syntax and semantics of Answer Set Programming, that is, disjunctive logic programming with strong negation and negation as failure, under the stable model semantics (Gelfond and Lifschitz, 1991).

Syntax

ASP language is based on *constants*, *predicate symbols* and *variable symbols*. A *term* is either a variable or a constant, whereas basic elements of ASP programs are *atoms*. An atom $p(t_1, \dots, t_n)$, is expressed by a *predicate* p of arity n having $t_1, \dots, t_n$ terms. A *classical literal* l can be either a positive atom p , or a negated atom $\neg p$. When using *Negation as failure* (NAF) literals can be positive literals, denoted as l , or negative literals, denoted as $\text{not } l$. Literals are said to be *ground* if no variables appear in them. An ASP program is composed of a finite set of (possibly *disjunctive*) rules, where each rule r is of the form:

$$a_1 \vee \dots \vee a_n \leftarrow b_1, \dots, b_k, \text{not } b_{k+1}, \dots, \text{not } b_m \quad (1)$$

Here $a_1, \dots, a_n, b_1, \dots, b_m$ are classical literals and $n \geq 0, m \geq k \geq 0$. The disjunction $a_1 \vee \dots \vee a_n$ is the *head* of r , whereas the conjunction $b_1, \dots, b_k, \text{not } b_{k+1}, \dots, \text{not } b_m$ is the *body* of r . A *normal rule* has precisely one head literal (i.e. $n = 1$), whereas if $n > 1$ the rule is called *disjunctive*. An *integrity constraint* is a rule without head literals (i.e. $n = 0$), whereas a *fact* is a rule with an empty body (i.e. $k = m = 0$). In order to simplify the notation, in this last case the symbol " $\leftarrow$ " is omitted. The following symbols can be useful as short hands for denoting the head $H(r) = \{a_1, \dots, a_n\}$ and the body $B(r) = B^+(r) \cup B^-(r)$ of a rule r , including the *positive body* $B^+(r) = \{b_1, \dots, b_k\}$ and the *negative body* $B^-(r) = \{b_{k+1}, \dots, b_m\}$.

Safety is an important property, which is required for all rules. A rule r is *safe* if every variable of r appears in at least one positive literal of the body.

A not-free ASP program $\mathcal{P}$ (i.e., such that it does not contain negative literals) is called *positive* (Observe that strong negation ($\neg$) may be present, instead), whereas a $\vee$ -free program $\mathcal{P}$ is called *normal logic program*.

Example 2.1: Consider the following program:

```

r1: root(a). edge(a,b). edge(a,c). edge(c,b). edge(c,d). edge(b,e). edge(d,a).
    node(a). node(b). node(c). node(d). node(e).
r2: inTree(X,Y)  $\vee$  outTree(X,Y)  $\leftarrow$  edge(X,Y), reached(X).
r3: reached(X)  $\leftarrow$  root(X)
r4: reached(Y)  $\leftarrow$  reached(X), inTree(X,Y).
r5:  $\leftarrow$  root(X), inTree(Z,X).
r6:  $\leftarrow$  inTree(X,Y), inTree(Z,Y), X  $\neq$  Z.
r7:  $\leftarrow$  node(X), not reached(X).

```

r_1 contains ground literals, which are also facts. r_2 is a disjunctive rule, whereas r_3 and r_4 are normal rules; r_4 is also recursive. Finally, rules r_5 – r_7 are constraints, where r_7 contains also a negative literal. $\square$

Semantics

Semantics of ASP is based on stable models formerly introduced in Gelfond and Lifschitz (1991).

Answer sets are defined over ground programs. Given a program $\mathcal{P}$ and the set $U_{\mathcal{P}}$ of all constants appearing in $\mathcal{P}$, let $B_{\mathcal{P}}$ indicate the set of all ground positive literals that can be obtained from predicates in $\mathcal{P}$ and constants in $U_{\mathcal{P}}$. The *ground instantiation* of a program $\mathcal{P}$ is the set $\text{Ground}(\mathcal{P})$ containing all possible ground rules that can be obtained by replacing each variable in $\mathcal{P}$ with constants in $U_{\mathcal{P}}$ for any rule r in $\mathcal{P}$.

The definition of answer sets is based on the notion of interpretations which are subsets of $B_{\mathcal{P}}$ satisfying certain properties. A positive literal l is true w.r.t. X if $l \in X$, otherwise it is false. A negative literal $\text{not } l$ is true whenever l is false. A rule r is satisfied if

$H(r) \cap X \neq \emptyset$ whenever all body literals are true w.r.t. X . An interpretation $X \subseteq B_P$ is a model if for every $r \in \text{Ground}(P)$ r is satisfied by X .

A model is an *answer set* for a positive disjunctive program $\mathcal{P}$, if it is minimal (under set inclusion) among all models for $\mathcal{P}$.

Now, in order to define answer sets for a general program $\mathcal{P}$, we need to introduce the *reduct* or *Gelfond-Lifschitz transform* of $\text{Ground}(P)$ w.r.t. a set $X \subseteq B_P$, which is the positive ground program $\text{Ground}(P)^X$, obtained from $\text{Ground}(P)$ by

- deleting all rules $r \in \text{Ground}(P)$ for which $B^-(r) \cap X \neq \emptyset$ holds;
- deleting the negative body from the remaining rules.

An *answer set* of a program $\mathcal{P}$ is a set $X \subseteq B_P$ such that X is an answer set of $\text{Ground}(P)^X$.

Example 2.2: Consider the program $\mathcal{P}$ of Example 2.1. $U_P = a, b, c, d, e$. Ground instantiations of rule r_3 are: $\text{reached}(a) \leftarrow \text{root}(a)$, $\text{reached}(a) \leftarrow \text{root}(b)$, $\text{reached}(a) \leftarrow \text{root}(c)$, ... $\text{reached}(e) \leftarrow \text{root}(c)$, $\text{reached}(e) \leftarrow \text{root}(d)$, $\text{reached}(e) \leftarrow \text{root}(e)$.

Observe that every answer set will contain the facts of $\mathcal{P}$. Constraints like r_5 prevent some interpretations to be closed and, consequently, models. As an example, every interpretation including $\text{root}(a)$ and $\text{inTree}(d, a)$ will be discarded.

$\mathcal{P}$ has two answer sets (we omit facts for simplicity):

$\{\text{inTree}(a, c), \text{inTree}(b, e), \text{inTree}(c, b), \text{inTree}(c, d), \text{outTree}(a, b), \text{outTree}(d, a), \text{reached}(a), \text{reached}(b), \text{reached}(c), \text{reached}(d), \text{reached}(e)\}$, and

$\{\text{inTree}(a, b), \text{inTree}(a, c), \text{inTree}(b, e), \text{inTree}(c, d), \text{outTree}(c, b), \text{outTree}(d, a), \text{reached}(a), \text{reached}(b), \text{reached}(c), \text{reached}(d), \text{reached}(e)\}$.

Observe that these are two *spanning trees* over the input graph defined by *edge* and *node* facts. $\square$

A Logic-Based Methodology to Knowledge Representation and Reasoning

ASP has been applied for solving a number of complex problems in several areas including databases and artificial intelligence. One of the advantages of ASP, as a knowledge representation and reasoning paradigm is the possibility to model problems and complex tasks in a declarative fashion.

Deductive database queries and complex reasoning tasks can be modeled by using a uniform solution over varying instances in the form of a fixed non-ground program coupled with input instances modeled by facts. More in detail, many reasoning tasks of comparatively high computational complexity can be solved in a canonical manner by following a knowledge representation methodology, called “Guess&Check” (Eiter et al., 2000; Leone et al., 2006).

In simple terms this methodology can be summarized as follows: a set of disjunctive rules (called the “guessing part”) is used to define candidate solutions; and another set of rules (called the “checking part”) imposes admissibility constraint to single out the solutions of the problem. Finally, a database of facts is used to specify an instance of the problem.

Basically, the answer sets of the combination of the input database with the guessing part, model “solution candidates”; the checking part filters candidates to guarantee that the answer sets of the resulting program represent precisely the admissible solutions for the input instance.

In what follows, we illustrate the usage of ASP for knowledge representation and reasoning by using two classical examples. In particular, we first show how to solve a classical problem in deductive database applications; then we adopt the “Guess&Check” methodology to solve well-known hard problems.

Reachability. A classical problem solved elegantly by deductive databases is called *reachability*. In more formal terms, given a directed graph $G = (V, E)$, the problem is to compute all pairs of nodes $(x, y) \in V \times V$ such that y can be reached from x by following a nonempty sequence of edges in E .

The input graph G is represented by the binary predicate $\text{arc}(X, Y)$, where a fact $\text{arc}(x, y)$ is in the input whenever $(x, y) \in E$ (i.e., G contains an arc from x to y). There is no need to represent explicitly V , since the nodes appearing in the transitive closure are implicitly given by these facts.

The solutions are modeled as follows:

$r_1: \text{reachable}(X, Y) \leftarrow \text{arc}(X, Y).$

$r_2: \text{reachable}(X, Y) \leftarrow \text{arc}(X, U), \text{reachable}(U, Y).$

where predicate $\text{reachable}(X, Y)$ will contain facts of the form $\text{reachable}(a, b)$ whenever b is reachable from a in G . Indeed, The first rule states that node Y is reachable from node X if there is an arc in the graph from X to Y , while the second rule states that node Y is reachable from node X if there exists a node U such that there is an arc from X to U and Y is reachable from U .

As an example, consider a graph represented by the following facts:

$\text{arc}(a, b), \text{arc}(b, c), \text{arc}(c, d).$

The program admits the single answer set $\{\text{reachable}(a, b), \text{reachable}(b, c), \text{reachable}(c, d), \text{reachable}(a, c), \text{reachable}(b, d), \text{reachable}(a, d), \text{arc}(a, b), \text{arc}(b, c), \text{arc}(c, d)\}$. The first three atoms are obtained by applying r_1 , while the other instances of reachable are obtained by applying r_2 .

N-Colorability. A classical NP-complete problem in graph theory is N-Colorability. Given a set of colors C and a finite directed graph $G = (V, E)$, does there exist a way of assigning precisely one color out of those in C to each node in V in such a way that nodes connected by an arc have assigned different colors?

The representation of the graph is analogous to the previous problem, and we add in the input a fact $color(c)$ for each color $c \in C$.

The following program models the *N-Colorability* problem:

```

 $r_1$ :  $node(X) \leftarrow arc(X, Y)$ .
 $r_2$ :  $node(Y) \leftarrow arc(X, Y)$ .
 $r_3$ :  $color(X, C) \vee differentColor(X, C) \leftarrow node(X), color(C)$ .
 $r_4$ :  $\leftarrow color(X, C1), color(X, C2), C1 < > C2$ .
 $r_5$ :  $\leftarrow color(X, C), color(Y, C), arc(X, Y)$ .

```

The first two rules compute the set of nodes out of the input that specifies all the arcs. Rule r_3 guesses an assignment of colors to nodes, whereas the remaining constraints ensure that only one color is assigned to each (rule r_4) and nodes connected by an arc have assigned different colors (rule r_5).

Hamiltonian Path. Given a finite directed graph $G = (V, E)$ and a node $a \in V$ of this graph, does there exist a path in G starting at a and passing through each node in V exactly once?

This is a classical NP-complete problem in graph theory. The representation of the graph is analogous to the previous problem, and we add in the input a fact modeling the starting node a as in instance of predicate *start*.

The following program models the *Hamiltonian Path* problem:

```

 $r_1$ :  $inPath(X, Y) \vee outPath(X, Y) \leftarrow arc(X, Y)$ .
 $r_2$ :  $reached(X) \leftarrow start(X)$ .
 $r_3$ :  $reached(X) \leftarrow reached(Y), inPath(Y, X)$ .
 $r_4$ :  $\leftarrow inPath(X, Y), inPath(X, Y1), Y < > Y1$ .
 $r_5$ :  $\leftarrow inPath(X, Y), inPath(X1, Y), X < > X1$ .
 $r_6$ :  $\leftarrow node(X), not\ reached(X), not\ start(X)$ .

```

The disjunctive rule (r_1) guesses a subset S of the arcs to be in the path, while the rest of the program checks whether S constitutes a Hamiltonian Path. The auxiliary predicate *reached* specifies the set of nodes which are reached from the starting node. This is very similar to the solution of reachability, but here *inPath* is made transitive using rule r_3 .

The requirements of an Hamiltonian Path are imposed in the checking part. In particular, r_4 and r_5 select solutions in which the set of arcs S selected by *inPath* is such that: (i) there must not be two arcs starting at the same node, and (ii) there must not be two arcs ending in the same node. Finally, r_6 acts so that all nodes in the graph are reached from the starting node.

Tools for Executing ASP Programs: Architecture and Assessment

The practical application of ASP has been made possible by the availability of efficient implementations. In this section we introduce the general architecture of ASP systems, (Kaufmann et al., 2016) and describe the ASP Competition, (Calimeri et al., 2016) a biannual event conceived to assess the state of the art in ASP evaluation.

Tools for Executing ASP Programs. The first reasonable implementations of the ASP language became available in the second half of the 1990ies. Since then the basic architecture of an ASP system is made of two main components: the Grounder (or instantiator) and the Solver (or model generator). In particular, the input program $\mathcal{P}$, usually read from text files, is first passed to the Grounder that implements a variable-elimination procedure. Basically, the grounder parses $\mathcal{P}$ and generates a ground program $Ground(\mathcal{P})$ that has the same answer sets as $\mathcal{P}$. The produced ground program can be exponentially larger in size with respect to $\mathcal{P}$; thus, concrete grounders employ intelligent procedures that aim at keeping the instantiated program as small as possible. The ground program produced by the Grounder is then evaluated by the Solver, which implements the non-deterministic part of an ASP system. Roughly, a Solver implements some backtracking algorithm to compute answer sets. Finally, once an answer set has been found, ASP systems typically print it in text format.

In the literature, several different techniques for implementing the Grounder and the Solver have been proposed. As a consequence, there are several alternative implementations one can resort to. Among the grounders we mention Gringo (Gebser et al., 2011) and i-DLV (Calimeri et al., 2017); whereas, among the more modern solvers we mention Clasp, (Gebser et al., 2011) WASP, (Alviano et al., 2015) and those from the lp2normal (Bomanson et al., 2014) family. Since, in practice, different combination of tools perform best in different application domains, the selection of the best evaluation strategy has been made automatic in portfolio and multi-engine solvers, such as Claspfolio (Hoos et al., 2014) and ME-ASP (Maratea et al., 2014). It is worth mentioning that, the easiest choice to execute an ASP program is the usage of a monolithic systems (i.e., a system that combines grounder and solver in the same tool), and in this case the most prominent alternatives are DLV, (Leone et al., 2006) and Clingo (Gebser et al., 2011).

Assessment of ASP Systems. The performance of ASP systems is evaluated in ASP Competitions since 2007 (Calimeri *et al.*, 2016). The ASP competitions aim at assessing and promoting the evolution of ASP systems and applications. Its growing range of challenging application-oriented benchmarks inspires and showcases continuous advancements of the state of the art in ASP.

In the following, we spotlight main aspects of the Sixth edition of the ASP competition (the most recent edition of the event at the time of this writing), and in particular we outline the improvements of participant systems carried out to assess the advancement of the state of the art. The competition was open in general to any ASP solving system, provided it is able to parse the standard format called ASP Core 2.0 (Calimeri *et al.*, 2016). Participant systems are run in a uniform setting, on a selection of instances taken from the official benchmarks suite, which is updated every edition with instances from various application domains. In particular, in the Sixth ASP Competition there were 13 competing ASP systems. The instance selection process, carried out according to a rigorous schema that ensures a balance of easy, hard, and very hard instances, ended up in the selection of 560 instances in total from 28 application domains. Each system was allotted 20 min per run, including the time for grounding, and solving. Up to 5 points could be earned per solved instance, corresponding to a perfect maximum total score of 2800. The first three places were taken by the top-performing systems from each team: the multi-engine system ME-ASP (Maratea *et al.*, 2014, 2015) with a score of 1971, the combined system WASP + DLV (Alviano *et al.*, 2015, 2014; Leone *et al.*, 2006) with score 1938, and LP2NORMAL + CLASP integrating dedicated preprocessing (Bomanson *et al.*, 2014) and search (Gebser *et al.*, 2015) with score 1760.

One of the main goals of an ASP competition is to measure the advancement of the state of the art. We report in the following the results of an empirical analysis of the state of the art in ASP solving that was published in Gebser *et al.* (2016). In this experiment the performance of the first three solvers occupying the podium position in the Fifth and the Sixth Competition have been compared on the instances of the more recent edition. Despite only one year has passed between the two events, the substantial improvements in solving technology were evident. All the participants of the Sixth Competition solved more instances than the overall winner of the Fifth edition (labeled CLASP-2014). Notably, the updated versions of LP2NORMAL + CLASP and WASP + DLV (wasp1.5 named the combination of wasp and dlw in 2014) could solve 35 and 171 more instances respectively, which corresponds to substantial improvements of 198%, and 114% respectively. It is also notable the performance of the me-asp system, that was able to solve more instances than any other by combining in a portfolio all solvers from the Fifth edition. This assessment proves that the advancement of the state of the art in ASP solving was consistent and continuous in the last few years.

Applications of ASP

ASP has been successfully applied for solving complex problems in several research areas (cf. (Erdem *et al.*, 2016) for a complete survey) such as Artificial Intelligence (Balduccini *et al.*, 2001; Gagli *et al.*, 2015) Databases (Manna *et al.*, 2015; Marileo and Bertossi, 2010) industrial applications (Grasso *et al.*, 2011) etc. To show the applicability in bioinformatics, in the following, we focus on the applications of ASP in this research area, such as phylogenies reconstruction, modeling biochemical reactions and genetic regulations, modeling biological signaling networks, prediction of protein structure, complex querying over biomedical ontologies and databases. In particular, ASP has been used to solve a number of problems connected to the reconstruction of phylogenies for specified taxa. In Brooks *et al.* (2007) ASP was used for reconstructing phylogenies for *Alcataenia* species; and the same methods have been extended for reconstructing phylogenetic networks in Erdem (2006). A general ASP-based solution to the supertree construction problem has been given in Koponen *et al.* (2015) and the validity of the proposed ASP-based method has been verified by computing a genus-level supertree for the family of cats (Felidae).

An ASP-based model of biochemical reactions and genetic regulations has been proposed in Gebser *et al.* (2011) to detect and explain inconsistencies between experimental profiles and influence graphs. As an example, they could find out inconsistencies in the profile data of SNF2 knock-outs by comparing it with the yeast regulatory network.

A model of a biological signaling network was proposed in Nam and Baral (2009) which can be used to generate hypotheses about the various possible influences of a tumor suppressor gene on the p53 pathway.

The problem of predicting the structure of a protein has been approached with ASP in Campeotto *et al.* (2015) with the goal of finding a folding in the 2D square lattice space, that maximizes the number of hydrophobic contacts between given amino acids.

Methods for solving the Haplotype Inference by Pure Parsimony (HIPP) problem and its variations with ASP have been studied in Erdem *et al.* (2009).

We finally mention some applications of ASP to query answering over biologic, and biomedical databases. In particular, ASP was used in the NMSU-PhyloWS project (Le *et al.*, 2012) to query the repository CDAOStore of phylogenies with the goals of finding similarities w.r.t. distance measures, or for computing optimal clades for taxa in specified trees. In Esra and Öztok (2015) ASP has been used to answer complex queries over biomedical ontologies and databases. The ASP-based query answering systems can find answers and explanations to some complex queries related to drug discovery over databases such as BIOGRID, CTD, DRUGBANK, PHARMGKB, and SIDER and DISEASE ONTOLOGY.

Future Directions and Closing Remarks

In this article we introduced a powerful knowledge representation and reasoning formalism, that can be used to solve complex problems. In particular, we have introduced language and tools for Answer Set Programming (ASP). We have also shown that ASP

has the potential to play a crucial role in the solution of complex problems in bioinformatics, as it is witnessed by a number of successful applications in this area. As far as future directions are concerned, given that ASP provides both a declarative problem solving framework for combinatorial optimization problems and a knowledge representation and reasoning framework for knowledge-intensive reasoning tasks, it can be envisaged that a number of similar problems and challenges can be effectively approached and solved with ASP. Real applications often point out weaknesses of implementations, and ASP systems will be subject of future developments and extensions to effectively answer to the computational challenges arising in bioinformatics.

Introduction

The study of biological data certainly found its wide application in improving the sustainability of biological processes and hence the life on our planet. There is increasing interest in investigating computational methods for storing, managing, and analysing biological data which is growing exponentially. ML techniques serve as potential computational methods for extracting knowledge from the biological data (Larranaga *et al.*, 2006). ML experiments are paramount for bioinformatics as they aid in building models for detecting patterns within biological inputs like genomes, health-care data, protein structures etc. and analysing them. ML models learn from and make predictions on biological data (Witten *et al.*, 2016), with a functional approximation (Eq. (1)).

$$f(X) = Y \quad (1)$$

where X acts as biological data, f acts as a functional approximation over X and Y is the new derived biological knowledge. ML techniques are applied mainly in two biological domains:- (i) OMIC Sciences and (ii) Systems Biology (Fig. 1; Larranaga *et al.*, 2006).

ML techniques can be applied in analysing data from varied biological areas (Tarca *et al.*, 2007) as follows:

- Predicting the gene locations and their biological roles
- Predicting protein or molecular functions and studying interactions.
- Predicting diseases from molecular samples
- Sequence analysis
- Drug discovery
- Phylogenetic analysis
- Analysing biological images and components and the list is dynamic and extensible.

However, data analysis is complex as a huge amount of heterogeneous data is generated in the biological processes. The current research needs include development and application of ML algorithms to further study the voluminous and varied biological compositions (Tarca *et al.*, 2007). The aim of this article is to provide insights on ML methods useful in bioinformatics categorizing their varied types, challenges, and applications to provide a general context on the importance of computational techniques in biological sciences for naïve readers. The article is organised as follows. Section “Definition” defines ML and its phases with enlisting of different kinds of ML. Section “Feature Selection and Extraction in Bioinformatics” is focussed on introducing feature selection procedures. Various representative algorithms for modelling ML procedures are described in Section “Representative ML Algorithms”. Section “Assessment of the Performance of ML Algorithms” describes validation indexes for supervised and unsupervised ML models. Section “Other Emerging Paradigms in ML” enlists the emerging paradigms of ML and Section “Machine Learning Software” enlists the emerging ML Tools useful in computational biology. Section “Applications in Bioinformatics and Systems Biology” highlights few of the biological applications of ML with key highlights on literature.

Definition

The term “Machine Learning” was coined by Arthur Samuel at IBM in 1959 (Kohavi and Provost, 1998). The field has evolved from the applied computational statistics, pattern recognition and artificial intelligence. Hence, ML is defined as an ensemble of computational techniques for predictive data analytics facilitating data-driven decisions based on learning from input data.

(1) Training and Testing

ML consists of two major phases of training and testing the model which aid in creating a system to answer the biological questions (Fig. 2).

In the training step, data is trained to incrementally improve the model’s ability for predicting the output. Once the training is complete, the built model is tested against data that has never been used for training and is evaluated to judge how the model might perform in the real-world application (Carbonell *et al.*, 1983).

(2) Types of Machine Learning

ML algorithms are categorized based on predictive, descriptive, or inductive modelling of functional tasks. The main categories are listed as follows (Ayodele, 2010).

- Supervised Learning:** This class is mainly targeted at predictive modelling of tasks based on predefined input data-labels (Kotsiantis *et al.*, 2007). A predictive model is constructed from training data to model functional relationships or dependencies between the input data and the target prediction output (labels). The target values (predictions/labels) for new data is based on the learned relationships from the previous data inputs. The supervised learning algorithms dealing with categorical targets are known as “classification” algorithms and the algorithms for continuous data are termed as

Fig. 1 Applications of ML in biology.

Fig. 2 Phases of ML modelling.

“regression” algorithms. The commonly used classification algorithms are: Decision trees, Random forests, Support vector machines, Neural Networks, Nearest Neighbor, and Naïve Bayes (Kotsiantis *et al.*, 2007). The regression algorithms include linear or multivariate regression logistic regression with lasso, ridge, or elastic-net penalties (Kotsiantis *et al.*, 2007; Carbonell *et al.*, 1983).

- ii. *Unsupervised Learning*: This is purely a data-driven approach and aids in descriptive modelling of data. There are no predefined target labels as described in supervised learning (Ayodele, 2010; Hyvärinen *et al.*, 2010). The unsupervised techniques are applied directly to the input data to detect patterns, rules or summaries which aid in deriving new meaningful insights from the data. Algorithms used to group input data points based on data properties into different classes (labels) are known as “clustering algorithms”. Some of the clustering algorithms include k-means, k-medoids, and hierarchical clustering (Hyvärinen *et al.*, 2010). The mining of association between different input variables (items) in data, aids in determining patterns and frequent item-sets and is known as “Association Rule Mining” (Karthikeyan and Ravikumar, 2014).
- iii. *Semi-Supervised Learning*: This kind of learning is a blend of supervised and unsupervised learning (Chapelle *et al.*, 2009). Labelled data requires expertise and unlabelled data is cheap; semi-supervised learning gains from both the factors. It is also known as inductive learning. The learning progresses using distances and densities in between data points and assumptions on the underlying distribution of data, such as points which are close to each other distance-wise, are more likely to share an output label.

Feature Selection and Extraction in Bioinformatics

Bioinformatic studies are influenced by choice of biological features and their importance across the huge number of biological samples. A natural question to ask is “which biological features are significant for predicting biological roles in analysis?” Feature selection is the process of reducing the size of biological sample space to attain only relevant biological features for improving the quality of the results is constantly emerging as a pre-cursor step in large-scale biological analyses. The commonly used strategies for feature selection are (Saeys *et al.*, 2007):- (a) Filter based approaches; (b) Wrapper based approaches and (c) Embedded Approaches.

Filter methods extract features based on general data properties, for example ranking features based on their significance or correlation with biological roles. The filters incorporate various methods such as correlation-based feature selection, ranking features based on probabilistic conditional distribution such as entropy, dependency between the joint distribution of the biological features and biological roles (Saeys *et al.*, 2007). Wrappers evaluate biological features by estimating their accuracy using a machine learning scheme itself (Kohavi and John, 1997). They are based on the interaction between an ML algorithm and the training data using some search algorithm or an optimization in either a forward or backward search over the biological input data. Embedded methods tend to in-cooperate the feature selection strategy as part of the ML model (Kohavi and John, 1997).

Fig. 3 A sample decision tree.

Feature extraction techniques like Principle Coordinate analysis (PCoA), Principle Component Analysis (PCA), Linear Discriminant Analysis (LDA) etc., transform the data to a different space, reducing dimensionality and are useful in analysing and visualizing the data in bioinformatics (Saeyns *et al.*, 2007).

Representative ML Algorithms

This section presents a brief introduction to a list of representative ML algorithms for biological predictions.

(1) Classification

In a classification problem, the set of data items are needed to be divided into groups known as classes. Given an instance of the item-set, a class is assigned according to some of the features of items and a set of classification rules. Some of the famous classification algorithms are listed below.

a. Decision Trees

Decision trees represent hierarchical representation of relationships between various features in the biological data. The method depends on classifying a set of features through a series of questions on a tree traversal path, in which the answer of the current question determines the answer to the next question (Quinlan, 1986). Decision tree builds classification in the form of a tree structure as shown in Fig. 3. The sample figure (Fig. 3), depicts the risk of health hazards to a person depending on smoking status and diet plan. The leaf nodes represent the samples classified into categories/classes of subjected to less risk and more risk hazards. Popular decision tree algorithms, include ID3 (Iterative Dichotomiser 3), C4.5 Algorithm, CART (Classification and Regression Tree), CHAID and QUEST (Almana and Aksoy, 2014). The method simplifies complex relationships between input biological features and target classes by dividing original input variables into significant subgroups.

b. Random Forest and XGBoost

Random Forest creates the forest structure with randomized construction and integration of several decision trees to classify item sets. To classify a new sample based on biological features, each decision tree gives a classification and the tree "votes" for a class are counted for final decisions (Breiman, 2001). It takes a random sample of observation and randomly chosen initial items/features to build a decision tree model. The process is repeated many times and the final prediction is a function of each prediction derived from different constituent decision trees. This final prediction can simply be the mean of each prediction. It captures the variance of several input trees and hence supports good predictive ability even over large biological data sets. To make Random Forest faster, XGBoost (Chen and Guestrin, 2016) is proposed, which exploits out-of-core computation and scales to larger data with the least amount of computing resources (Chen and Guestrin, 2016).

c. Support Vector Machines

The algorithm starts with plotting each data/feature item as a point in n-dimensional space with the value of each nth feature being a coordinate in geometric plane. For example, if there are two sample features (e.g., age and smoking status) w.r.t. an individual, the two variables are plotted in a two-dimensional space; where each point has two co-ordinates known as Support Vectors (Drucker *et al.*, 1997). The aim of this model is to find a line that splits the data between the two classes such that it maximizes the distance-gap between the closest point in each of the two groups (Fig. 4). Hence, the line acts as a classifier.

d. Artificial Neural Networks

Artificial Neural Networks (Graupe, 2007), originated from the idea of mathematically modelling the human brain. In an Artificial Neural Network, the input biological features are forwarded to sequenced layers of neurons (the processing units), also known as nodes, in combination with associated weight thresholds (Eq. (2)). The combination drives the

Fig. 4 Support vector machines.

Fig. 5 The neural networks.

ability to perform classification at output layer (Graupe, 2007; Fig. 5).

$$OUTPUT = \sum W_i X_i \text{ where } i = 0 \text{ to } n_o : \text{ of inputs, } W_i : \text{ weights and } X_i : \text{ inputs} \quad (2)$$

The processing units are organised in layers (shown in Fig. 5). In multilayer perceptron the values of the parameters (weights) may be determined by the backpropagation algorithm.

Shen and Chou (2006), integrated multiple classifiers to create an ensemble for genomics studies to obtain a more concrete result in classification of samples.

(2) Clustering

Clustering is based on intrinsic grouping, i.e., it is a technique which arranges biological items into groups such that the members of a group are most like each other and are dissimilar to the items belonging to other groups. The groups are known as clusters. Clustering methods can be classified into following main categories (Gan et al., 2007).

- *Partitioning methods:* Given n data items, these methods are based on creating k partitions of the data, where each partition represents a cluster such that $k \leq n$. These use an iterative shifting or relocation technique for moving items from one cluster group to another, till the best results are achieved. Two popular heuristics methods are (Gan et al., 2007):- (i) K-means algorithm and (ii) K-medoids algorithm.

- **Hierarchical methods:** A hierarchical method is based on hierarchical decomposition of the given set of items. A hierarchical method could be either agglomerative (bottom-up) or divisive (top-down), based on the direction of decomposition. In each successive step, a cluster is split into smaller clusters, until eventually, each object is in any of the cluster. Other dominant methods for clustering are:- (i) *Density based methods*, which consider clustering until the density (number of items) in the cluster exceeds a given threshold and may result in clusters of an arbitrary shape; (ii) *Grid based methods*, which are based on quantizing and clustering the items into finite number of cells forming a grid structure and hence depends on number of cells in each dimension in the quantized space; (iii) *Model based methods* that hypothesize clustering by constructing model for each of the clusters and finding the best fit of the data to the given model (Gan et al., 2007).

(3) Association Rule Mining

The process is associated with link analysis, alternatively also known as affinity analysis or association analyses. It facilitates the data-mining tasks of uncovering relationships amongst items within the biological samples. An association rule is a model that captures the relationships among items based on their patterns of co-occurrence across samples. An implication expression for the association rule is of the form $X \rightarrow Y$, where X and Y are feature item-sets (Karthikeyan and Ravikumar, 2014). The analysis is useful in bioinformatics; e.g., to find co-expressed genes with their functions, to determine combinations of structural properties in biomolecules, to find patterns of frequently co-occurring annotations derived with frequent itemset in protein interactions, etc.

(4) Deep Convolutional Nets

The biologically inspired and enhanced variant of Neural Networks is *Convolutional Neural Deep Networks (ConvNets)*. They consider the input as mostly images and their architecture have neurons arranged in 3 dimensions of activation volume: width (w), height (h), depth (d), unlike 2D Neural Networks (Fig. 6; Anon, 2017).

Such networks have successfully been used in drug discovery. Potential treatments could be derived from predicting the interaction between molecules and biological proteins. The first deep learning Neural Network, *AtomNet* was introduced for structure-based rational drug design (Wallach et al., 2015).

Assessment of the Performance of ML Algorithms

Assessment methods determine the extent to which ML models demonstrate the desired learning outcomes. The main objective is to learn an ML model that attains a good generalization performance by maximizing the prediction accuracy or, in other words, minimizing the probability of making a wrong biological prediction. The most important mathematical modelling for evaluating supervised ML prediction is driven by a confusion matrix. A confusion matrix and related measures are shown in Fig. 7 (Powers, 2011). A confusion matrix is an $Num \times Num$ matrix, where *Num* represents the number of classes being predicted. In the given example (Fig. 7), *Num* is taken as 2 (i.e., binary classification case).

The quality of unsupervised learning (clustering) is determined by following numerical indexes (Halkidi et al., 2002):

- Cluster cohesion as the sum of the weight of all links between items within a cluster (Intra-Cluster Index)
- Cluster separation as the sum of the weights between items in the cluster and items outside of the cluster (Inter-Cluster Index)

Other Emerging Paradigms in ML

This section enlists two of the emerging ML techniques.

- (1) **Reinforcement Learning:** This field of ML is inspired by the systematic approach of behaviourism in psychology. The environment is majorly implemented as a Markov decision process (MDP) which relies on learning agents taking actions in a

Fig. 6 Difference between simple and deep neural net. Available at: <http://cs231n.github.io/convolutional-networks/>.

Confusion Matrix		Target			
		Positive	Negative		
Model	Positive	a	b	Positive Predicted Value	$a/(a+b)$
	Negative	c	d	Negative Predicted Value	$d/(c+d)$
		Sensitivity $a/(a+c)$	Specificity $d/(d+b)$	Accuracy = $(a+d)/(a+b+c+d)$	
AUC = plot between sensitivity and (1- specificity)					

Where a denotes the number of true positives (positive samples correctly classified as positive), b denotes the number of false negatives (positive samples incorrectly classified as negative), c represents the number of false positives (negative samples incorrectly classified as positive), and d represents the number of true negatives (negative samples correctly classified as negative).

Fig. 7 Assessment measures for supervised learning.

Fig. 8 The process of reinforcement learning.

given environment and moving from one problem state to another (Kaelbling *et al.*, 1996). Each action is associated with a reward. The aim of a reinforcement learning agent is to collect maximum rewards as possible by performing actions. To summarize, MPD consists of following (Puterman, 2014; Fig. 8):- a set of environment and agent states, S ; a set of actions, A , of the agent; the probability of transition from one state to another state belonging to S under an action $a \in A$; the reward while transition; rules describing the agents' observations.

- (2) *Extreme Machine Learning (ELM)*: ELM proposed by Huang *et al.* (2004), is a novel generalized learning algorithm for single-hidden-layer Neural Networks. In ELM, the input weights and hidden biases are generated randomly, and the output weights are calculated by regularized Least-Square method, which makes it faster. The model learns the output weights amounting to a linear model. There is no tuning of modelling parameters for propagation in the backward direction like in Neural Networks. Hence it is feed-forward Neural Network with only one hidden layer. Due to high performance, ELM is becoming a significant area in ML especially for pattern recognition in ML (Huang *et al.*, 2004).

Machine Learning Software

ML software/s have become integral part of data science solving problems of biological domain. The tools aid in data preparation, and predictive modelling. The four commonly used tools are listed below to enhance the learning experience for readers.

- (1) **RapidMiner**
RapidMiner, formerly known as YALE (Yet Another Learning Environment), was first developed in 2001 by Ralf Klinkenberg, Ingo Mierswa, and Simon Fischer at the Technical University of Dortmund in java programming language (Data-mining-blog.com, 2017). It serves as an open source Graphical User Interface (GUI) tool relying on a template-based block-diagram approach in which predefined blocks act as plug-ins. The product is based on ETL, i.e., extract, transform and load data phenomena. It was declared as the most popular data analytics software in 2016 by annual software poll conducted by KDnuggets (Jupp *et al.*, 2011). RapidMiner is suited for data related to biological Sciences. The RapidMiner Plugin for Taverna (Jupp *et al.*, 2011), allowed a mass application of ML tools to bioinformatics workflows (Data-mining-blog.com, 2017).
- (2) **BioWeka**
The Waikato Environment for Knowledge Analysis (Weka) supports various classification, regression, clustering algorithms, with various data pre-processing methods such as feature selection with good visualization (Hall, 1999). Gewehr *et al.* (2007), introduced bioinformatic methods to Weka as part of BioWeka project as shown in Fig. 9, which proved useful for biological studies.

Fig. 9 BioWeka. Reproduced from Gewehr, J.E., Szugat, M., Zimmer, R., 2007. BioWeka – Extending the Weka framework for Bioinformatics. *Bioinformatics* 23 (5), 651–653.

(3) MATLAB

MathWorks product MATLAB ([Uk.mathworks.com](http://uk.mathworks.com), 2017), provides an integrated environment for modelling and simulating biological systems. Bioinformaticians are using MATLAB and related toolboxes to perform data analysis over sequences, microarrays etc., mass spectrometry for measuring bio-chemical compounds, medical image processing, bio-statistics, and to simulate biological networks among other computations. The SimBiology library in MATLAB provides a graphical and modelling tool for systems biology and a specialized field of pharmacokinetics ([Uk.mathworks.com](http://uk.mathworks.com), 2017). The tool is widely used in automating the biological workflows with computational techniques. It is also useful to acquire real data from medical instruments (like heart rate recorder), cards, sensors, read or write biological data including signals, images, omics data from files, databases, web and excel for simulating biological systems with an intuitive graphical interface. MATLAB is proved to be useful in biological visualizations. For example, BrainMaps are used to analyse massive, high-resolution brain image data at BrainMaps.org ([Uk.mathworks.com](http://uk.mathworks.com), 2017).

As an alternative to MATLAB, various open source programming languages like R, Python and Scala are emerging to support various ML packages, useful in biological systems ([Shameer et al., 2017](#); [Faghri et al., 2017](#)).

(4) R-Project

R-Project is emerging as a most powerful statistical tool and offers various useful packages for analysis and visualization of biological data. The Bioconductor-project ([Gentleman, 2006](#)), is an effective platform for the analysis of genomic data. Bioconductor supports various useful packages such as:- *ape* package aids in analysis of phylogenetics and evolution, *ade4* is useful for multivariate analysis of genetic markers, *picante* is useful for ecological studies, *affy* supports analysis of Affymetrix gene chip data at prob level, *DEGseq* is an R package for identifying differentially expressed genes from RNA sequence data, *ShortRead* is helpful in exploration of high throughput sequence data, *WGCNA* is an R package for weighted correlation network analysis, *limmaGUI* is aimed at linear modelling of microarray data, *DeepBlueR* is helpful in epigenomic analysis in R, etc. (Bioconductor.org, 2017). Recently cancer-subtypes has been developed for identifying molecular subtype identification, validation, and visualization ([Xu et al., 2017](#)).

Applications in Bioinformatics and Systems Biology

ML is revolutionizing the world of biological sciences. ML plays an important role in analysing the interpreting data from biological including DNA, RNA, protein structures, gene sequences (ATGC bases), microarray gene expression data, biological networks and pathways, biological signals, and biological images. Hence it supports both OMIC sciences and systems biology. The varied applications are highlighted in [Fig. 10](#). The field is also playing major role in detection of diseases and optimizing biological measures therapeutically. ML has been applied to diagnose and predict critical diseases like cancer prognosis ([Kourou et al., 2015](#)), autism diagnostic ([Bone et al., 2015](#)), chronic disease ([Chen et al., 2017](#)), etc. to support man-kind. [Plummer et al. \(2015\)](#), reviewed three bioinformatics pipelines:- (i) MG-RAST: Meta Genome Rapid Annotation using Subsystem Technology; (ii) QIIME: Quantitative Insights into Microbial Ecology; (iii) *mothur* for the analysis of preterm gut microbiota using 16S rRNA gene sequencing data.

ML methods are useful for analysing microarray gene expression data ([Pirooznia et al., 2008](#)). [Lin et al. \(2002\)](#), applied supervised ML in functional genomics for conserving codon composition of ribosomal protein coding genes in tuberculosis. Pharmacogenomics is an emerging field for understanding genetics in the context of how a patient respond to drugs. [Gacesa et al. \(2016\)](#) highlighted that ML can differentiate venom toxins from other proteins having non-toxic physiological functions. Biological sciences are not only useful in human health but also in field of agriculture to improve soil quality, crop yield, cattle health, etc. [Wassan et al. \(2017\)](#) contributed towards metagenomics pipeline for the prediction of impact of feed additives on cattle health.

Fig. 10 Applicative areas of ML in bioinformatics.

Final Remarks

In this article, we summarized various ML techniques and tools that are useful for analysing biological data, ranging from training, testing, and validating the input data for novel predictions. The data science tools such RapidMiner, BioWeka etc.; ML techniques such as classification, clustering, association analysis etc.; various bioinformatics ML code libraries such as BioPython, BioPerl, BioRuby, and R-Bioconductor are also useful in varied applications of biology. An application of ML techniques helps to focus on finding the most plausible patterns and predictions from biological data including Next Generation Sequencing data analysis, gene assembly, annotation, phylogeny, molecular structural modelling, and gene expression analysis. The future in related context lies in developing scalable ML algorithms for bioinformatics as biological inspired data is growing exponentially (Faghri *et al.*, 2017).

Introduction

The analysis of complex systems, i.e., systems consisting of several interdependent and interacting entities that determine the system behavior, requires the exploitation of new and more effective solutions able address issues ranging from the definition of appropriate modeling formalisms to the use of advanced system analysis methods. Such kinds of systems can be classified in two main categories: Artificial Systems (ASs) that are built by humans and Natural Systems (NSs), already existing in nature without the intervention of humans. In particular,

- Examples of Artificial Systems are nowadays called Cyber-Physical Systems (CPSs) ([Chen and Lu, 2018](#)) or System of Systems (SoSs) ([Garro and Tundis, 2015](#)). Here different components belonging to various application domains (such as Software, Mechanical, Electrical, Electromechanical, and so on), which are originally conceived for working in isolation for a specific purpose, and are integrated in a common environment in order to achieve one or more complex goals ([Sampigethaya and Poovendran, 2012](#); [Zhabelova and Vyatkin, 2012](#)).
- Examples of Natural Systems are represented by Biological Systems (BSs) ([Anderson, 2015](#)), in which a complex network of biological entities belonging to different biological subsystems (such as the nervous system, circulatory system, respiratory system, and so on) work together in a synergistic manner.

Concerning the second example, Intelligent Systems represent a very promising solution in computational biology. They allow the development of complex applications centered on theoretical methods, for supporting data-analysis based on mathematical modeling, and computational simulation techniques for observing social systems and studying biological phenomena on the basis of the so-called emergent behavior ([Seekhao et al., 2016](#); [Adamatti, 2016](#)). Indeed, typically, in these systems it is not enough to observe and analyze the state and output of the single system or individual entity, but it is necessary to observe the way they interact and cooperate, in order to capture particular dynamics resulting from their interactions, which define their emergent behaviors.

It is clear that for such classes of systems, agents provide a suitable research approach, thanks to their key features of autonomy and cooperation. A key role, in the adoption of intelligent agents, is played by the environment, which represents the “problem space” in which the agents operate and in which the agents represent one possible resolution path. It is important to note that the environment can be partially or fully observable. Observability lets the agent retrieve information and perform computation on it in order to take decisions and consequent actions on the basis of the perceived information. Moreover, the environment can be deterministic or stochastic. As a consequence, if the environment is deterministic, its properties are well known and none of them are random, which means that the output of the model is fully determined by the values of its parameters and by its initial conditions. If the environment is stochastic, then some randomness and uncertainty is present in it.

Specific details about Intelligent Agents, Environment, and their Interactions are provided in the rest of the article.

Agents and Intelligent Agents

As stated in the previous section, different but similar definitions for agents have been provided in the literature. A weaker but more general definition of Agents, that may be suited to describe the extremely heterogeneous approaches encountered in the agent-based simulation context, is to see an Agent as an autonomous entity, having the ability to decide the actions to be carried out in the environment and interactions to be established with other agents, according to its perceptions and internal states.

In artificial intelligence, an Intelligent Agent (IA) is an autonomous entity that observes through sensors and acts upon an environment using actuators (i.e., it is an agent) and directs its activity towards achieving goals (i.e., it is “rational”, as defined in economics). Intelligent agents may also learn or use knowledge to achieve their goals. They may be very simple or very complex: a reflex machine such as a thermostat is an intelligent agent.

The most popular definitions of IA were provided (i) by [Smith et al. \(1994\)](#) who stated that “An agent is a persistent software entity dedicated to a specific purpose.”, (ii) by [Hayes-Roth \(1996\)](#) who said that “Intelligent agents continuously perform three functions: perception of dynamic conditions in the environment, action to affect conditions in the environment, and reasoning to interpret perceptions, solve problems, draw inferences, and determine actions”; (iii) by IBM, which said “Intelligent agents are software entities that carry out some set of operations on behalf of a user or another program with some degree of independence or autonomy, and in so doing, employ some knowledge or representation of the user’s goals or desires.”

According to the vision described by [Russell and Norvig \(1995\)](#) an IA can be seen as an entity in a program or environment capable of generating action. From a more technical perspective, an Intelligent Agent is an entity in a program or environment capable of generating actions ([Magedanz et al., 1996](#)). It uses perception of the status of the environment in order to make decisions about specific actions to take. The perception is represented by the capability or sensitiveness which is typically achieved by sensors; whereas the actions are the reactions to a particular status of phenomena that can depend on the most recent perception or on the entire history (sequence of perceptions). An Intelligent Agent uses and provides functions. A function can be a mathematical function that maps a sequence of perceptions into one or more actions, which is implemented as an agent program. The part of the agent that is in charge of taking an action is called an actuator.

Other important characteristics of agents include the following:

- *Rationality*: an agent is supposed to act in order to achieve its goals and does not act in such a way as to prevent its goals being achieved, at least insofar as its beliefs permit. A rational agent is one that can take the right decision in every situation on the basis of a set of criteria/tests, used to measure the level of performance in term of the success of the agent's behavior. Such performance measures should be based on the desired effect of the agent on the environment. In particular, the agent's rational behavior depends on (i) the performance measure that defines success; (ii) the agent's knowledge of the environment; (iii) the actions that it is capable of performing; (iv) the current sequence of perceptions. In general, for every possible perception sequence, the agent is expected to take an action that will maximize its performance measure.
- *Autonomy*: an agent is able to take initiative and exercise a non-trivial degree of control over its own actions. Indeed, autonomy is the capacity to compensate for partial or incorrect prior knowledge, and it is usually achieved by learning. This is because an agent is not omniscient and, in practice, it does not know all the actual or possible outcomes of its actions. As a consequence, an exploration approach is necessary, through which an agent performs an action to gather information and to increase its perception

Based on such characteristics, well-known agent models have been identified such as Simple Reflex, Model-Based Reflex, Goal-Based, Utility-Based, and Learning.

- *Simple Reflex*: The decision of the action to take is only based on the current perception. The history and the perceptions gathered in the past are neglected. This model is based on *condition-action* rules. This model works if the environment is fully observable (stateless).
- *Model-Based Reflex*: this agent model works when the world is not fully observable. As a consequence, it is important that the agent remember previous observations about the parts of the environment which it cannot observe in a particular period of time. This requires a supporting model for representing the environment (stateful).
- *Goal-Based*: this agent model aims at driving the agent to achieve a specific purpose, and the action to be taken depends on the current state and on what it is trying to accomplish (the goal). Sometimes, achieving the goal requires a single action, in other cases the goal to be reached is complex and decomposed into multiple subgoals, each of which requires one or a set of actions. In this case, the achievement of all subgoals subsumes the achievement of the main goal. Usually in this case, strategies, planning, and sifting through a search space for possible solutions, are necessary.
- *Utility-Based*: this can be seen as a supporting or complementary model to the Goal-Based model previously described. In this case, the agent knows the utility function, which is continuously monitored and exploited to estimate the distance between the goal and the current state of the agent.
- *Learning*: this agent model has the capability of enriching its "knowledge" and abilities by observing and acting accordingly. This means that the agent is able to learn from past experiences in the environment to predict the future and, in some cases, (pro)actively affect the environment.

The next section focuses on the concepts of environment, the role that it plays, and its main properties.

Environment

While the notion of agent is obviously central to this subject, all of the most widespread definitions of agent at least mention the fact that a surrounding *environment* is present, for instance to provide percepts and a context in which actions are attempted. Whereas the awareness of the significance of the environment in which an intelligent agent is situated was already recognized in the earliest version of the most widely adopted book on Artificial Intelligence [Russell and Norvig \(1995\)](#), within the autonomous agents and multi-agent systems (MAS) research community the recognition of the environment as an explicit and essential part of a multiagent system required some time and a systematic analysis of the typical practice of researchers in the area. [Weyns et al. \(2007\)](#), in a foundational paper on this topic, provide the following definition:

The environment is a first-class abstraction that provides the surrounding conditions for agents to exist and that mediates both the interaction among agents and the access to resources.

The authors also highlight the fact that the environment is a first-class abstraction for agent oriented models not just providing the surrounding conditions for agents to exist, but also representing an exploitable design abstraction for building multiagent system applications.

Table 1 Example of different environments and their characterization

Example	Observable	Deterministic	Static	Discrete
Chess	Fully	Yes	Yes	Yes
Poker	Partly	No	Yes	Yes
Real-time strategy	Partly	No	No	No

Russell and Norvig, in the above cited book, provided several dimensions for the characterization of an environment, and in particular the most relevant in this context are:

- *observability*: agents can have complete or partial access to the state of the environment;
- *determinism*: in deterministic environments agents' actions have single, guaranteed effects;
- *dynamism*: in a static environment agents can assume that no change happens during their own deliberation;
- *discreteness*: discreteness can refer to different aspects of the environment, namely its state, the way time is represented and managed, and the perceptions and actions of agents; generally, in a discrete environment there are a fixed, finite number of actions and perceptions.

Examples of environments and their respective characterizations are shown in [Table 1](#). Clearly, the features of the environment heavily influence the design decisions about the agent architecture; it must also be clarified that it is sometimes possible to take a simplified but still acceptable perspective on certain aspects of an environment in order to actually come up with applicable and tractable solutions: for instance, to stay within the gaming example context, in a real-time strategic game the modeler could superimpose a discrete representation of the continuous environment to support the coordination of units patrolling an area.

Recently, [Russell and Norvig \(1995\)](#) also included an additional dimension of analysis that specifies whether the environment includes other agents and, in this case, also the cooperative or competitive attitude of agents (a more thorough analysis of the different types of interaction is provided by [Ferber \(1999\)](#)).

A more recent analysis, provided by Weyns *et al.*, instead of describing inherent features of an environment, considers it from the perspective of a design abstraction supporting the activities of the modeler or engineer. Their analysis considers that three different levels of support can be provided by the environment:

- *basic level*, essentially just enabling the agents to directly access their deployment context;
- *abstraction level*, filling the conceptual gap between the agent abstraction and low-level details of the deployment context (e.g., wrapping physical or software resources and providing access at agents' level of abstraction);
- *interaction/mediation level*, supporting both forms of regulation to the above mentioned resources, as well as mediating the interactions among agents to support forms of coordination.

Whereas most agent oriented platforms provide abstraction level support, support of the interaction/mediation level is generally not as comprehensive and systematic, as indicated by relatively recent works discussing meta-models for multiagent systems that explicitly include abstractions enabling this kind of high-level support (see, e.g., [Omicini et al., 2008a](#)).

Weyns *et al.* also stress the fact that the environment has a fundamental role in *structuring* the system: this is particularly relevant for applications such as the simulation of biological entities in which the defined model actually represents a physical spatial structure (e.g., portions of tissues of a human body), but it can also be relevant in situations in which the model must consider other conceptual structures such as organizational or societal ones (e.g., roles, groups, permissions, policies). Whenever the computational model needs to represent a physical environment, and to explicitly consider its spatial aspects and dynamics, even without involving the modeled agents, the need for a precise and systematic model of perception and action is even more apparent than in other situations. From this perspective, models such as the one described by [Ferber and Müller \(1996\)](#) represent relevant examples of a specific form of high-level support supplied by the environment model.

Finally, once again especially but not exclusively in the biological context, it is often the case that the modeler needs to consider distinct but related dynamics that are more reasonably or effectively represented by employing different spatial or temporal scales. The overall multiagent model could, therefore, include different environmental representations at different scales, potentially characterized by different features according to the above introduced schema, or the overall model could even employ completely different styles in a hybrid approach (as discussed by [Dada and Mendes \(2011\)](#)): the different dynamics must then be properly coupled by means of some form of interaction among the different submodels and scales.

Actions and Interactions

The notion of *action* directly contributes to the definition of agent: literally, *the one who acts*. Understanding the reciprocal *dependencies* between individual agents and their surrounding environment – either physical or computational, therein including the space-time fabric – amounts to understanding which kind of actions produce which kind of *effects* – either intended or not – and on *whom* – either another agent or (a portion of) the environment.

The distinction regarding the kind of actions taken as reference throughout the article is made by focusing on the *purpose* of an action (Kirsh and Maglio, 1994):

epistemic actions are meant to acquire/release information, and may or may not have a direct practical effect, either intended or not *practical actions*, on the contrary, are meant to directly affect a subject, and may or may not have not a direct epistemic effect, either intended or not.

From this stems the distinction w.r.t. the kind of effects caused by actions:

epistemic effects directly cause the acquisition/release of information *practical effects* directly cause a change in a subject

As the reader may notice, epistemic actions may have practical effects (possibly, not intended and indirect), and practical actions may have epistemic effects in turn (again, possibly not intended and indirect). Despite how odd this may seem, the popular distinction categorizing actions as either *communicative* or *practical* has been proven to be misleading by Conte and Castelfranchi (1995), who argue that practical actions are in all respects also communicative when they have an intended (although possibly implicit) communicative effect.

Anyway, epistemic actions are *mostly* based on *communication*, be it explicit or not, thus they likely require (FIPA, 1996) – at the very least:

- A *content language*, that is, a language for “talking about things”.
- A set of *communicative acts*, that is, the acts through which “communication happens”.

Besides, fruitful communication among *computational* agents is likely to require the content language to be shared among participants in a “conversation”, to require the communicative acts to have a well-defined shared semantics, and the conversations to adhere to prescribed interaction protocols guaranteeing some desired properties.

As far as practical actions are concerned, they are *mostly* based on *practical behaviors*, and thus are likely to require:

- *Perception* (Russell and Norvig, 1995) of the acting agent’s surroundings for detecting the subject of the action;
- *Practical reasoning* grounded upon *bounded rationality* (Bratman, 1987), to plan the course of actions to undertake in order to achieve a goal while considering feasibility, expected utility, likelihood of success, and the cost of the actions themselves.

Regardless of the purpose and the effects of actions, it is apparent that actions are influenced by their subject – who is it, an agent or the environment? – as well as by their surroundings – where and when is the action taking place? Which properties influence the action’s outcome, feasibility, etc.? In other words, actions are *situated* w.r.t. their *context*, which brings us to the next subsection.

Situated (Inter)Action

Situatedness is the property of being immersed within an *environment* (Suchman, 1987), that is, the property of being potentially influenced and, in turn, potentially capable of affecting someone or something.

Actions are then situated by definition: regardless of whether they are practical or epistemic, they have a target, a source, happen at a given time (and possibly have a duration, and/or a delay), affect a given space (either virtual or physical), and cause some change (at least, if successful) either intended or not (“side effects”). Thus, agents too are situated: through actions, they can be regarded as being “active” at a given time, in a precise space, for a given observer (e.g., the target of the action), either because through actions they affected someone or something, or because their course of action has been influenced by someone or something.

It is worth noting that situatedness directly relates to the notions of *perception* and *practical reasoning*: perception is the tool by which agents and the environment become *aware* of their surroundings (Russell and Norvig, 1995), and thus are potentially influenced by the activities therein; practical reasoning is the tool by which agents (and an intelligent environment? (Mariani, 2016) can *deliberate* about how to affect something or someone (Bratman, 1987).

Inter-actions then, are situated too, following the same reasoning: each of the participants in the interaction is situated, then the (inter-)actions they carry out *reciprocally affecting* each other are situated too – both because they are actions, although (possibly) *communicative*, and because the acting participants are situated. Besides, interactions also may be situated because they are *mediated* by some means external to the participants: e.g., the environment. In this case, since the environment is situated due to its very nature, any interaction it enables and constrains may be regarded as situated as well, through the properties of the environment – the flow of time, the topology of space, the existence of resources, and properties with their own dynamics.

Whether or not (inter-)actions are mediated by the environment, they always represent a *social* relationship between the parties involved, which brings us to the next subsection.

Social (Inter)Action

Castelfranchi discusses how the complex and distributed dependencies within the agents in a MAS – mostly regarding goals (Dennett, 1971), delegation and trust (Castelfranchi and Falcone, 1998) – are fundamental to the definition of intelligence as a social construct (Castelfranchi *et al.*, 1993). In particular, the notion of *social action*, which is meant to reconcile individual cognitive processes and social coordination, provides a conceptual foundation which all MAS social issues (cooperation, collaboration, competition) can be grounded on.

Not by chance, in fact, one of the first relevant acts of the Foundation for Intelligent Physical Agents (FIPA) – a world-wide organization devoted to agent-based technology – was to define a reference semantics for the FIPA Agent Communication Language (FIPA-ACL), and to also define the semantics of social actions – in this case, intended as message exchanging – which is now the standard for agent-oriented middleware (Bellifemine *et al.*, 2001).

Along the same lines, the many different kinds of social relationships expressed by social interactions have been recognized as deserving a first-class abstraction in the process of MAS engineering, especially when it comes to governing the *space of interactions*, a task which originated a whole research thread, branded *coordination models and languages* (Ciancarini, 1996). Accordingly, the SODA methodology explicitly accounts for *societies of agents* (Omicini, 2001), in line with the A&A meta-model (Omicini *et al.*, 2008a) which adds the notion of *artefact* – in particular, coordination artefacts – as a means for agents to augment their capabilities, both practical and cognitive, and to structure the societies they live in – as well as the MAS environment.

Agents in Bioinformatics and Computational Biology

It is not the aim of this article (nor it is considered actually possible) to provide a compact but comprehensive review of the most notable applications of agent models and technologies to bioinformatics and systems biology. Nonetheless, it is reasonable and useful to give an idea of the *categories* or areas of these applications.

First of all, as also noted in a general resource describing the state of the art and providing perspectives on agent-based computing (Luck *et al.*, 2005), simulation represents an application context in which the notion of autonomous agents have become almost ubiquitous: An *et al.* (2009), for instance, present a review of agent-based modeling approaches to translational systems biology, but a plethora of applications to other relevant areas and approaches could also be cited. What it worth noting is that, very often, the notion of agent employed in these works takes a very different perspective from the one provided by the most widely accepted definitions of intelligent agents, being more focused on studying the resulting or emergent behavior of the local actions and inter- actions of relatively simple agents, than on defining and employing knowledge-level agents involved in complicated patterns of coordination.

The latter, however, has become instead quite relevant to the design and implementation of solutions for managing specific parts or the overall workflow of scientists working in the field, in a more general e-science perspective, also as a consequence of results from the subfield of Agent Oriented Software Engineering (see, e.g., Jennings, 2001). For instance, Miles (2006) presents an example of an application in which agent-based approaches have been employed for performing data curation in the bioinformatics area, whereas Bartocci *et al.* (2007) describe a web-based Workflow Management System for bioinformatics that employs an agent-based middleware.

Whereas the previous systems, although actually applied to the specific fields of systems biology and bioinformatics, essentially accomplish quite general tasks, tasks that are quite specific to these research fields can also be fruitfully supported by agent-oriented applications: for instance, Garro *et al.* (2004) and Armano *et al.* (2006) describe agent-based approaches to the prediction of protein structures, in which agents are associated with different predictors, and their results are combined to achieve an improved collective overall performance compared the performance of the individual predictors.

Closing Remarks

The domain of Intelligent Agents is growing at an exponential rate (Singh *et al.*, 2017). The basic concepts offer powerful solutions for designing a variety of agent-based solutions. Over the past three decades, significant advances have been made in the domain, specifically pertaining to agent interaction and communication in complex distributed systems. The technology is now finding acceptance in commercial applications as well as in complex and mission critical applications. Efforts to improve the technology are still going on, and many issues, such as defining the limits on trust, intelligence, and their applicability are yet open. The full potential of agents is yet to be realized.

Introduction

The agent is a metaphor that was natively originated in Artificial Intelligence (AI) (see works from Newell, and others). Its characteristics changed when the emphasis was put on multi-agent systems, rather than on single agents. A key event in the history of multi-agent systems was the recognition that agents can be used fruitfully to model and implement distributed systems. The creation of Foundation for Physical Intelligent Agents (FIPA) originates from the recognition that multi-agent systems are a novel and promising approach for the implementation and deployment of distributed systems. It is important to recognize that many applications of agents exist outside AI, because tools and techniques, which are intended to support one, are not necessarily good for the other. In particular, nowadays, multi-agent systems have two major applications outside of their traditional role in AI:

- Engineering of distributed systems, with the introduction of agent-oriented software engineering (AOSE) (e.g., agent-oriented methodologies, agent-oriented programming languages).
- Agent-based modeling and simulation (ABMS), which is what this article is mostly about.

Agents are entities that observe their environment and act upon it so as to achieve their own goals ([Russell and Norvig, 2003](#); [Wooldridge, 2009](#)). Two fundamental characteristics of agents are *autonomy* and *situatedness*. Autonomy means that agents have a sense-plan-act deliberative cycle, which gives them control of their internal state and behavior. Whereas, agents are situated because they can sense, perceive, and manipulate the environment in which they operate. The environment could be physical or virtual and it is understood by agents in terms of (relevant) data. Autonomy implies proactivity, i.e., the ability of an agent to take action toward the achievement of its objectives, without being solicited to do so.

From a programming perspective, agent-oriented programming was introduced by Shoham as “a specialization of *object-oriented programming*” ([Shoham, 1993](#)). The difference between agents and static objects is clear. Citing Wooldridge ([Wooldridge, 2009](#), Section 2.2): (1) objects do not have control over their own behavior (this is summarized by the well-known motto “Objects do it for free; agents do it because they want it”), (2) objects do not exhibit flexibility in their behavior, and (3) in standard object models there is a single thread of control, while agents are inherently multi-threaded.

The agent-based paradigm also differs from the Actor Model ([Hewitt et al., 1973](#)) (and from Active Objects, largely inspired by the latter). Actors, in fact, do not have neither goals nor purposes, even though their specification includes a process. Agents, instead, exploit their deliberative cycle (as control flow), possibly together with the key abstractions of belief, desire, and intention (as logic), so as to realize algorithms, for example, processes for acting in their environment to pursue their goals. In other words objects “do it” for free because they are data, agents are processes and “do it” because it is functional to their objectives.

The environment, in which agents are situated, does not exhibit the kind of autonomy that is typical of agents although it may evolve, also thanks to an internal process. Its activity, however, is not meant to pursue a goal and this makes environments more similar to active objects.

The binomial agent–environment is formalized by modeling approaches like ([Demazeau, 1995](#)), where the environment is seen as providing “the surrounding conditions for agents to exist and that mediates both the interaction among agents and the access to resources”, and in particular by the Agent & Artifact meta-model ([Omicini et al., 2008](#)).

A system comprising a number of possibly interacting agents is called a *multiagent system*. At this level, it is widely recognized that further abstractions become handy, like organizations and interactions, aimed at enabling a meaningful and fruitful coordination of the autonomous and heterogeneous agents in the system. Thus, agents are not only situated in a physical environment, they are also situated in a social environment where they get into relationships with other agents and are subject to the regulations of the society they belong to. A normative multiagent system is “a multiagent system together with normative systems in which agents on the one hand can decide whether to follow the explicitly represented norms, and on the other the normative systems specify how and in which extent the agents can modify the norms” ([Boella et al., 2007](#)). The impact on the agent’s deliberative cycle is that agents can reason about the social consequences of their actions.

Multi-Agent Systems

There is no single definition for the word agent, and there is no single definition for the term multi-agent system (MAS). Notably, major accepted definitions share commonalities, such as the way the agents interact in a system: via the shared environment, via structured messages (ontologies, interaction protocols). Indeed, a MAS can be defined in terms of interacting entities, and in

particular the agents. Communication may vary from simple forms to sophisticated ones. A simple form of communication is that restricted to simple signals, with fixed interpretations. Such an approach was used by Georgeff in multi-agent planning to avoid conflicts when a plan was synthesized by several agents. A more elaborate form of communication is by means of a blackboard structure. A blackboard is a shared resource, usually divided into several areas, according to different types of knowledge or different levels of abstraction in problem solving, in which agents may read or write the corresponding relevant information for their actions. Another form of communication is by message passing between agents.

Autonomy is another major characteristic of agents, when defining a MAS, also referred to as “self-organized systems”, enabling them to find the best solution for their problems “without intervention”. The main feature which is achieved when developing multi-agent systems, is flexibility, since a multi-agent system can be added to, modified and reconstructed, without the need for detailed rewriting of the application. The MAS also tends to prevent propagation of faults, self-recover and be fault tolerant, mainly due to the redundancy of components.

It is extremely important to distinguish between Automatic and Autonomous systems. Automatic systems are fully pre-programmed and act repeatedly and independently of external influence or control. It can be described as selfsteering or self-regulating and it is able to follow an externally given path while compensating for small deviations caused by external disturbances. However, it is not able to define the path according to some given goal or to choose the goal dictating its path. Whereas, Autonomous systems, as a MAS, are selfdirected toward a goal in that they do not require outside control, but rather they are governed through laws and strategies that clearly make a difference between traditional and multi agent systems. If machine learning techniques are utilized, autonomous systems can develop flexible strategies for themselves by which they select their behavior.

More in detail, *norms* are a fundamental ingredient of multi-agent systems that govern the expected behavior toward a specific situation. Through the norms, the desirable behaviors for a population of a natural or artificial community is represented. Indeed, they are generally understood as rules indicating actions that are expected to be pursued that are either obligatory, prohibitive, or permissive based on a specific set of facts. According to [Hollander and Wu \(2011\)](#), norms have been used to indicate constraints on behavior ([Shoham and Tennenholtz, 1992](#)), to create solutions to a macrolevel problem ([Zhang and Leezer, 2009](#)), and to serve as obligatory ([Verhagen, 2000](#)), regulatory, or control devices for decentralized systems ([Savarimuthu et al., 2008](#)). The most common norms are:

- Conventions, which are natural norms that emerge without any enforcement ([Villatoro, 2011](#)). Conventions solve coordination problems when there is no conflict between the individual and the collective interests; for example, everyone conforms to desired behavior. Essential Norms are used to solve or ease collective action problems when there is a conflict between an individual and the collective interests ([Villatoro, 2011](#); [Villatoro et al., 2010](#)). For example, the norm not to pollute urban streets is essential in that it requires individuals to transport their trash, rather than dispose of it on the spot, an act that benefits everyone.
- Regulative Norms. Regulative norms are intended for regulating activities by imposing obligation or prohibition in performing an action.
- Constitutive Norms, which are affirmed to produce new goal norms or states of affairs, for example, the rules of a game like chess.
- Procedural Norms that are categorized as objective and subjective. Objective procedural norms represent the rules that express how decisions are really made in a normative system, while subjective procedural norms represent the instrument for individuals working in a system, for instance, back-office procedures.

Coordination is another distinguishing factor of a MAS. In fact, an agent exists and performs its activity in a society in which other agents exist. Therefore, coordination among agents is essential for achieving the goals and acting in a coherent manner. Coordination implies considering the actions of the other agents in the system when planning and executing one agents actions. Coordination allows agents to achieve the coherent behavior of the entire system. Coordination may imply cooperation and in this case the agent society works toward common goals to be achieved, but may also imply competition, with agents having divergent or even antagonistic goals. In this later case, coordination is important because the agent must take into account the actions of the others, for example, competing for a given resource or offering the same service.

Another characterizing feature of a MAS is its *emergent behavior*. Emergent behavior in agents is commonly defined as behavior that is not attributed to any individual agent, but is a global outcome of agent coordination ([Zhengping et al., 2007](#)). This definition emphasizes that emergent behavior is a collective behavior. There are also other definitions. Emergent behavior is that which cannot be predicted through analysis at any level simpler than that of the system as a whole Emergent behavior, by definition, is what’s left after everything else has been explained ([Dyson, 1997](#)). This definition highlights the difficulty in predicting and explaining emergent behavior. If the behavior is predictable and explainable, then it will not be treated as emergent behavior and approaches could be designed to handle the behaviors. Emergence is also defined as the action of simple rules combining to produce complex results ([Rollings, 2003](#)). This definition states that the rules applied to the individuals can be quite simple, but the collective behavior of the group may turn out to be quite complex and unpredictable. Researchers have designed experiments to demonstrate this kind of situation. While it is true that all behavior comes from individuals, the interactions are what make things difficult to understand. Emergent behavior is essentially any behavior of a system that is not a property of any of the components of that system, and emerges due to interactions among the components of a system. Borrowing from biological models such as an ant colony, emergent behavior can also be thought of as the production of high level or complex behaviors through the interaction of multiple simple entities. Some

examples of emergent behaviors: Bee colony behavior where the collective harvesting of nectar is optimized through the waggle dance of individual worker bees; Flocking of birds cannot be described by the behavior of individual birds; Market crashes cannot be explained by "summing up" the behavior of individual investors.

Further details about multi-agent systems can be founded in Baldoni *et al.* (2010).

Agent-based Modeling and Simulation

Agent Based Modeling and Simulation (ABMS) refers to a category of computational models invoking the dynamic actions, reactions and intercommunication protocols among the agents in a shared environment, in order to evaluate their design and performance and derive insights on their emerging behavior and properties (Abar *et al.*, 2017). Agents and multi-agent systems are entities that can be effectively used to model complex systems made of interacting entities. This is why they have been adopted to study biological and chemical systems, especially when the systems become too complex for the analytic tools available from Chemistry, Physics and Mathematical Physics. The fact that agents and multi-agent systems are abstractions with executable counterparts, the agents and the multi-agent systems that many tools support, contributed to suggest the use of agent technology to simulate biological and chemical systems. The size of simulated systems, and the high level of accuracy of simulated phenomena, calls for dedicated tools capable enabling the domain expert to describe simulations with little, or no, interest on the engineering issues related to distributed systems. Agent-based technology provides such tools and it supports domain experts in the construction of effective distributed systems with minimal emphasis on the inherent issues of large-scale distributed systems. Notably, even if dedicated tools are available, it is common to adopt tools designed to support agent-oriented software engineering in the scope of ABMS. In particular, a number of agent-based tools to support modeling and simulation of complex and/or distributed systems are available (Allan, 2009):

1. Netlogo: it is a multi-agent programmable modeling environment which allows the simulation of natural and social phenomena. It is particularly well suited for modeling complex systems developing over time. Indeed, modelers can give instructions to hundreds or thousands of "agents" all operating independently. This makes possible to explore the connection between the micro-level behavior of individuals and the macro-level patterns that emerge from their interaction. It comes with a large library of existing simulations, both participatory and traditional, that one can use and modify in different domains such as social science and economics, biology and medicine, physics and chemistry, and mathematics and computer science. In the traditional NetLogo simulations, the simulation runs according to rules that the simulation author specifies. A further feature of NetLogo is HubNet, a technology that lets you use NetLogo to run participatory simulations. HubNet adds a new dimension to NetLogo by letting simulations run not just according to rules, but by direct human participation.
2. FLAME: it is a generic agent-based modeling system which can be used to development applications in many areas. Models are created based upon a model of computation called (extended finite) state machines. The framework can automatically generate simulation programs that can run models efficiently on HPCs. It produces a complete agent-based application which can be compiled and built on the majority of computing systems ranging from laptops to HPC super computers. Furthermore, FLAME provides a Model Library which is a collection of relatively simple models that illustrate the use of FLAME in different applications.
3. AnyLogic: it is a simulation tool that supports all the most common simulation methodologies in place today: System Dynamics, Process-centric (AKA Discrete Event), and Agent Based modeling. Its visual development environment significantly speeds up the development process. It has applicational models in ManufacturingLogistics, Supply ChainsMarkets, Competition Business Processes Modeling Healthcare, Pharmaceuticals Simulation Pedestrian Traffic Flows Information, Telecommunication Networks Simulation Modeling Social Process, Marketing Simulation Asset Management, Financial Operations with Simulation Modeling Warehouse Operations and Layout Optimization.
4. Repast: The Repast Suite is a family of advanced, free, and open source agent-based modeling and simulation platforms that have collectively been under continuous development for many years. Repast Symphony is a richly interactive and easy to learn Java-based modeling system that is designed for use on workstations and small computing clusters. An advanced version is called Repast for High Performance Computing, which is a lean and expert-focused C++-based modeling system, that is designed for use on large computing clusters and supercomputers.
5. Jason: It is an interpreter for an extended version of AgentSpeak, that has been one of the most influential abstract languages based on the BDI architecture. Jason implements the operational semantics of that language, Strong negation, so both closed-world assumption and open-world are available. Annotations in beliefs are used for meta-level information and annotations in plan labels. One of the best known approaches for the development of cognitive agents is the BDI (Beliefs-Desires-Intentions) architecture. It provides the possibility to run a multi-agent system distributed over a network.
6. Framsticks: it is a three-dimensional life simulation project. Both mechanical structures (bodies) and control systems (brains) of creatures are modeled. It is possible to design various kinds of experiments, including simple optimization, co-evolution, open-ended and spontaneous evolution, distinct gene pools and populations and modeling of species and ecosystems. Users of this software work on evolutionary computation, artificial intelligence, neural networks, biology, robotics and simulation, cognitive science, neuro-science, medicine, philosophy, virtual reality, graphics, and art.
7. Gephi: it is an interactive visualization and exploration platform for all kinds of networks and complex systems, dynamic and hierarchical graphs. It allows (1) Exploratory Data Analysis: intuition-oriented analysis by networks manipulations in real time;

- (2) Link Analysis: revealing the underlying structures of associations between objects, in particular in scale-free networks; (3) Social Network Analysis: easy creation of social data connectors to map community organizations and small-world networks; (4) Biological Network analysis: representing patterns of biological data; (5) Poster Creation: scientific work promotion with hi-quality printable maps. It works mainly with metrics related to centrality, degree (power-law), betweenness, closeness, density, path length, diameter, HITS, modularity, clustering coefficient.
- 8. Stanford Network Analysis Platform (SNAP): it is a general purpose, high performance system for analysis and manipulation of large networks. It easily scales to massive networks with hundreds of millions of nodes, and billions of edges. It efficiently manipulates large graphs, calculates structural properties, generates regular and random graphs, and supports attributes on nodes and edges.

This is a list of the most popular simulation tools that can be used to model, simulate and analyzes complex systems by adopting agent oriented paradigm.

Agent-Oriented Software Engineering

Since its early days in late 1960s, *software engineering* has been constantly facing the problem of better understanding the sources of complexity in software systems. Over the last three decades, the complexity of interactions among parts has been progressively identified as one of the most significant sources of such a complexity. Software systems that contain a – possibly large – number of interacting parts are critical, especially when the graph of interactions changes dynamically, parts have their own thread of control, and parts are engaged in interactions governed by complex protocols (see, e.g., [Wooldridge and Ciancarini \(2001\)](#) for an in-depth discussion). As a consequence, a major research topic of software engineering has been the development of techniques and tools to understand, model, and implement systems in which interactions is the major source of complexity. This has led to the search for new computational abstractions, models, and tools to reason and to implement MASs, which have been recognized as prototypical examples of such systems. *Agent-Oriented Software Engineering* (AOSE) is an emerging paradigm of software engineering that has been developed to target the inherent complexity of analysing and implementing MASs (see, e.g., [Bergenti et al. \(2004\)](#) for a comprehensive reference on the subject). A number of AOSE methodologies have been proposed over the last two decades, and ([Kardas, 2013](#)) provides a recent survey of the state of the art of such methodologies.

Besides methodologies, the research on AOSE have been constantly interested in delivering effective tools to implement MASs. *Agent platforms* are examples of such tools intended to offer generic runtime environments for the effective deployment and execution of MASs. A number of platforms have been proposed over the years, and ([Kravari and Bassiliades, 2015](#)) proposes a recent attempt to enumerate the platforms that survived the test of time. One of the most popular agent platforms is *Java Agent DEvelopment framework* (JADE), as described in [Bellifemine et al. \(2007\)](#), which consists of a middleware and a set of tools that help the development of distributed, large-scale MASs. JADE is widely used for industrial and academic purposes and it can be considered as a consolidated tool. Just to cite a notable industrial example, JADE has been in daily use for service provision and management in Telecom Italia for more than six years, serving millions of customers in one of the largest and most penetrating broadband networks in Europe (see [Bergenti et al. \(2015\)](#) for further details). In order to effectively address the inherent issues of the high-profile scenarios that agent platforms target, specific tools are needed to assist the development of complex functionality, and to promote the effective use of the beneficial features of agent technology as a software development technology. Nevertheless, approaching AOSE with the help of agent platforms alone is often perceived as a difficult task for two main reasons. First, the continuous growth of agent platforms has been increasing their inherent complexity, and the number of implementation details that the programmer is demanded to master for the construction of MASs is equally grown. Second, the choice of mainstream programming languages as the unique option to use agent platforms is now considered inappropriate in many situations because such languages do not natively offer the needed abstractions for the effective concretization of AOSE.

The interest in *agent programming languages* dates back to the introduction of agent technologies and, since then, it has grown rapidly. As a matter of fact, agent programming languages turned out to be especially convenient to model and develop complex MASs. Nowadays, agent programming languages represent an important topic of research and they are widely recognized as important tools in the development of agent technologies, in contrast with mainstream languages, that are often considered not suitable to effectively implement AOSE. Agent programming languages are usually based on specific agent models and they aim at providing specific constructs to adopt such models at a high level of abstraction. The features of the various agent programming languages proposed over the years may differ significantly, concerning, for example, the selected agent mental attitudes (if any), the integration with an agent platform (if any), the underlying programming paradigm, and the underlying implementation language. Some classifications of relevant agent programming languages have already been proposed to compare the characteristics of different languages and to provide a clear overview of the state of the art. [Bădică et al. \(2011\)](#) classifies agent programming languages on the basis of the use of mental attitudes. According to such a classification, agent programming languages can be divided into: *Agent-Oriented Programming* (AOP) languages, *Belief Desire Intentions* (BDI) languages, hybrid languages – which combine the two previous classes – and other languages – which fall outside previous classes. It is worth noting that such a classification recognizes that BDI languages follow the *agent-oriented programming* paradigm, as defined in [Shoham \(1993\)](#), but it reserves special attention to them for their notable relevance in the literature. [Bordini et al. \(2006\)](#) proposes a different classification, where languages are divided into declarative, imperative, and hybrid. Declarative languages are the most common because they focus on automatic reasoning, both from the AOP and from the BDI points of view. Some relevant imperative languages have

also been proposed, and most of them were obtained by adding specific constructs to existing procedural programming languages. Finally, the presence (or absence) of a host language is an important basis of comparison among agent programming languages.

Even if early proposals dates back to late 1990s, AOSE is still at an early stage of evolution. While there are many good arguments to support the view that agents represent an important direction for software engineering, there is still need of actual experience to underpin these arguments. Methodologies and tools to support the deployment of MAS are beginning to become accepted for mission-critical applications, but slowly. Although a number of agent-oriented analysis and design methodologies have been proposed, there is comparatively little consensus among them. In most cases, there is not even agreement on the kinds of concepts the methodology should support. But, the research on AOSE is still active, and it has been recently revitalized by the view of AOSE in terms of *model-driven development*, as summarized in Kardas (2013).

Guidelines/Perspectives

Agents and multi-agent systems have been used to study and to simulate complex systems in different application domain where physical factor are present for energy minimizing, where physical objects tend to reach the lowest energy consumption possible within the physically constrained world. Furthermore, MAS have been intensively exploited for the analysis through simulation of biological and chemical systems. The literature reports on various successful uses of the abstractions and of their executable tools. Notably, the study of the benefits and the costs of adopting agents and multi-agent systems to support scientific studies of biological and chemical systems has not been approached extensively.

A well-known application field, where agents and MAS have been successful exploited regarding the study of biological phenomena, is the protein synthesis, a common and relevant phenomenon in nature. In this field, several approaches for predicting the three-dimensional structure of proteins are, for instance, available in literature Jennings *et al.* (1998). Several of them exploit the chemical or physical properties of the proteins (e.g., Standley *et al.* (1998), Dudek *et al.* (1998) work on energy minimization whereas Galaktionov and Marshall (1995), Sabzekar *et al.* (2017) uses intra-globular contacts); other ones use evolutionary information (Piccolbon and Mauri, 1998). Some tools for the prediction of the three-dimensional structure of proteins have been presented in Douguet and Labesse (2001), Gough *et al.* (2001), Meller and Elber (2001).

This shows that the autonomy of agents, their normed freedom of interaction, and the possibility of deploying large-scale systems with minimal care on issues related to distributed systems are few of the major benefits of approaching modeling and simulation of complex systems with agents. Furthermore, they closely represent how natural systems work by distributing a problem among a number of reactive, autonomous, deliberative, pro-active, adaptive, possibly mobile, flexible and collaborative entities. All these properties make agent technology more suited than other ones (e.g., a distributed system, an artificial intelligent system) for facing the challenges and high level of complexity of biological system and related phenomena.

Introduction

Many engineering and scientific problems require finding a solution that is optimal with respect to a predefined metric. Identifying an optimal solution with a mathematical guarantee is only possible when the Karush-Kuhn-Tucker (KKT) conditions are met (Horst and Pardalos, 2013). However, this is not always possible when gradient information is not available, the metric is difficult to compute, or the mathematical formulation of a problem is not available (e.g., simulators). In this case, we do not look for solutions with guaranteed optimality, instead we accept satisfactory solutions that are only putative or locally optimal. This is a common approach for solving optimization problems in science and engineering, and a plethora of algorithms have been proposed in the literature, both deterministic and stochastic. However, while deterministic methods can converge to a global optimum when certain conditions are met, stochastic methods are faster and more effective in practice, although they have weak convergence properties.

In this article, we present two stochastic optimization methods, namely Simulated Annealing (SA, Kirkpatrick *et al.*, 1983) and Genetic Algorithms (GA, Holland, 1975), which do not require gradient information to find putative optimal solutions to an arbitrary optimization problem and are straightforward to implement. The article is structured as follows; in Section Global Optimization, we give a brief overview of the fundamentals of global optimization; in Section Stochastic Optimization Algorithms, we outline the basic design principles of stochastic optimization methods, while in Sections Simulated Annealing and Genetic Algorithms we present the Simulated Annealing (SA) and the Genetic Algorithms (GAs), respectively. Finally, in Section Closing Remarks, we provide a brief comparative analysis of the two methods.

Global Optimization

Global optimization is the task of finding the set of parameters, $\mathbf{x}$, associated with the optimal value of an objective function, f , under a set of constraints, g . While local optimization looks for the optimal solution in a subregion of the feasible space, Ω , global optimization seeks an optimal solution in the entire feasible space. The change in scope between local and global optimization has tremendous theoretical consequences. Indeed, the $P \neq NP$ conjecture implies that there are no general algorithms to solve a global optimization problem in time polynomial in the problem description length (Neumaier, 2004).

Despite such strong theoretical limitations, in many engineering and scientific problems, finding the global optimal solution is not necessary; in practice, it is often sufficient to find a solution that improves the best known result. This is especially true for optimization problems where the objective and constraint functions are the output of simulators, when estimating the gradient is not possible, or numerical methods are not stable (Conn *et al.*, 2009). These problems belong to the class of black-box optimization problems, and many derivative-free algorithms have been proposed for this class of problems. Black-box functions are ubiquitous in science and engineering; for instance, in electronics, simulators that estimate the behavior of a circuit are treated as black-box functions, whereas in biology, an experiment is often modeled as a black-box function due to the lack of descriptive mathematical models.

We adopt a general formulation of an optimization problem subject to box, equality and inequality constraints, which tries to unify the canonical form with the extended formulation of black-box optimization introduced in Audet *et al.* (2010). Without loss of generality, we assume the problems are formalized as global minimization problems.

Let f be a function $f: \mathbb{R}^n \rightarrow \mathbb{R}$. A global optimization problem is defined as follows:

$$\begin{aligned} \min_{\mathbf{x} \in \Omega} \quad & f(\mathbf{x}) \\ g_k(\mathbf{x}) \quad & \leq \quad 0 & k = 1, \dots, l \\ h_z(\mathbf{x}) \quad & = \quad 0 & z = 1, \dots, m \\ \mathbf{x} \quad & \in \quad \mathbf{B} \text{ s.t. } \{b_i^- \leq x_i \leq b_i^+ | i = 1, \dots, n\} \end{aligned} \tag{1}$$

where n is the size of the problem, and the i -th variable, x_i , is bounded by b_i^- , b_i^+ , which are the lower and upper bound, respectively. $g_k: \mathbb{R}^n \rightarrow \mathbb{R}$ denotes a set of inequality constraints of size l , whereas $h_z: \mathbb{R}^n \rightarrow \mathbb{R}$ is a set of equality constraints of size m . Ω denotes the feasible region; if $\mathbf{x} \in \Omega$, then $\mathbf{x} \in \mathbf{B}$ and $g(\mathbf{x}) \leq 0$, $h(\mathbf{x}) = 0$ for all constraints. In general, each constraint is reformulated either in terms of equality or inequality to zero; this is a simple and convenient reformulation, which does not change the feasible region Ω .

Our definition accounts for different types of variables, including free variables ($x_i \in [-\infty, \infty]$), nonnegative variables ($x_i \in [0, \infty]$), and binary variables ($x_i \in [0, 1]$).

The constraint functions are usually classified as relaxable or unrelaxable; unrelaxable constraints are those constraints that a solution must not violate to be feasible. Conversely, relaxable constraints represent the degree of constraint violation of a solution. Relaxable constraints are often added as penalty terms to the objective function. An alternative approach is to reformulate the problem as a multi-objective optimization problem, where the relaxable constraints are modeled as additional objective functions. An additional class of constraints is the class of hidden constraints; this class includes those solutions, $\mathbf{x}$, in the feasible region, Ω , for which the objective function cannot be computed. This is a common scenario when the output is a simulator, which might fail to evaluate a solution despite its feasibility. If the problem defines a set of constraints and bounds s.t. $\mathbf{x} \notin \Omega$ for all $\mathbf{x}$, then the problem is deemed unsolvable and $\Omega = \emptyset$.

In our formulation, we assume that our problem is a single objective optimization problem, thus the objective function returns a single output value. A similar framework can be defined for multi-objective optimization problems, but it is outside the scope of this article. An extensive review on multi-objective optimization algorithms has been published by [Coello et al. \(2007\)](#).

Stochastic Optimization Algorithms

Although black-box global optimization problems cannot be solved exactly, several algorithms have been developed to identify satisfactory solutions to many practical problems.

Global optimization algorithms can be divided into two main classes ([Neumaier, 2004](#)); complete and incomplete search algorithms. Complete search methods can rigorously find all solutions to a global optimization problem if there are finitely many. Conversely, incomplete search algorithms are heuristic methods able to locate a putative optimal solution using heuristics. We will focus on incomplete search methods; an extensive introduction to complete search algorithms is presented in [Neumaier \(2004\)](#).

Heuristic global optimization methods include deterministic and stochastic algorithms; while the former comes with a theoretical convergence guarantee when the objective function meets specific mathematical conditions, the latter exploits stochastic sampling strategies to identify a putative optimal solution. It is important to point out that deterministic methods do not guarantee the identification of the global optimum, and the mathematical conditions for convergence can be rarely verified for black-box functions. An in depth review of deterministic global optimization methods is presented in [Floudas and Pardalos \(2008\)](#).

A plethora of stochastic methods have been proposed for global optimization, mostly based on two frameworks; Monte Carlo sampling and population-based sampling. Two algorithms have found applications in many engineering and scientific problems: Simulated Annealing (SA, [Kirkpatrick et al., 1983](#)) and Genetic Algorithms (GA, [Holland, 1975](#)). In the last 40 years, these methods have proven to be successful in identifying solutions to many optimization problems [Mavridou and Pardalos \(1997\)](#) where complete search methods are simply not feasible or deterministic algorithms perform poorly. SA and GA should be considered as two families of algorithms rather than distinct methods; indeed, although the underlying ideas have remained basically unaltered, there are several problem-specific implementations for both algorithms.

In the next sections, we describe in detail these two classes of algorithms and some of the most effective implementations.

Simulated Annealing

Simulated Annealing (SA, [Kirkpatrick et al., 1983](#)) is a global optimization method belonging to the class of Monte Carlo samplers. SA is able to locate a putative optimal solution of a function, f , by alternating a random sampling step with a probabilistic selection strategy. Specifically, SA is a Monte Carlo importance sampling technique, which was initially used to solve large scale physics integrals ([Metropolis et al., 1953](#)), and later in combinatorial optimization by [Kirkpatrick et al. \(1983\)](#). In their seminal paper, [Kirkpatrick et al. \(1983\)](#) also showed how statistical mechanics can be exploited to find satisfactory solutions to complex optimization problems. In this section, we describe the basic SA algorithmic framework and how to use statistical mechanics to study the behavior of this method.

Let f be a function $f: \mathbb{R}^n \rightarrow \mathbb{R}$. SA alternates a sampling and selection step as described in [Alg. 1](#).

The algorithm starts by initializing a candidate solution, $\mathbf{x}$, at random ([Alg. 1](#), line 1); this initial candidate solution can be replaced by providing an initial solution obtained from domain experts or other optimization methods. SA then picks a new candidate solution, $\hat{\mathbf{x}}$, at random from the neighborhood of the current optimum, $\mathbf{x}$. To do that, SA uses a generating function $N(\mathbf{x}): \mathbb{R}^n \rightarrow \mathbb{R}$; in the case of continuous optimization, this is typically a multi-variate probability distribution [Alizamir et al. \(2008\)](#). As for standard Monte Carlo sampling methods, the generating function is selected such that the ergodic hypothesis is verified, therefore ensuring all possible solutions are equiprobable.

SA accepts the new solution, $\hat{\mathbf{x}}$, if this improves the current value of the objective function; however, it also accepts worse solutions probabilistically following a negative exponential distribution controlled by a temperature parameter, T , ([Alg. 1](#), line 5–6). Initially, T is set to T_{init} ; T is then updated at each iteration according to an update function, $U: \mathbb{R} \rightarrow \mathbb{R}$, also called the cooling schedule. The probability of accepting a worse solution is controlled by the current temperature and the difference in the objective function, ΔE , for the two solutions, $\mathbf{x}$ and $\hat{\mathbf{x}}$.

Typically, SA stops when an arbitrary low temperature is reached ([Alg. 1](#), line 3).

Algorithm 1: Simulated annealing (SA)

```

1:    $\mathbf{x} \leftarrow \text{Initialize}()$ 
2:    $T \leftarrow T_{\text{init}}$ 
3:   while  $T \geq T_{\text{min}}$  do
4:      $\hat{\mathbf{x}} \leftarrow N(\mathbf{x})$ 
5:      $\Delta E \leftarrow \exp(-(f(\hat{\mathbf{x}}) - f(\mathbf{x}))/T)$ 
6:     if  $\Delta E \leq \text{Random}(0,1)$  then
7:        $\mathbf{x} \leftarrow \hat{\mathbf{x}}$ 
8:        $T \leftarrow U(T)$ 
9:   return  $\mathbf{x}$ 

```

The probabilistic acceptance criterion of SA mimics the physical annealing process (Kirkpatrick *et al.*, 1983), which is a thermal process used to obtain low energy states of a solid in a heat bath. Interestingly, the annealing process can be simulated on a computer using Monte Carlo sampling (Chandler, 1987; Aarts and Lenstra, 1997). For this reason, many interesting properties of SA can be analyzed using concepts from statistical mechanics.

Given a solid in state s_i with energy E_i ; let s_j be a state obtained from s_i by applying a random perturbation. Let E_j be the energy of the solid in state s_j ; if $\Delta E = E_j - E_i$ is negative, the new configuration is accepted, otherwise the new state is accepted with probability:

$$P(s_i) = \exp(-\Delta E/k_B T) \quad (2)$$

where T is the temperature and k_B is the Boltzmann constant (Aarts *et al.*, 2005); This probabilistic acceptance function is the standard Metropolis criterion. The solid can reach thermal equilibrium at each temperature if T is decreased sufficiently slowly. Indeed, the probability of a solid of being in state s_i with energy E_i at temperature T is given by the Boltzmann distribution:

$$P(s_i) = \frac{\exp(-E_i/k_B T)}{\sum_j \exp(-E_j/k_B T)} \quad (3)$$

where the sum goes over all the possible states configurations Aarts *et al.* (2005).

Using this statistical mechanics framework, a solution $\mathbf{x} \in \mathbb{R}^n$ for an optimization problem with objective function, f , is equivalent to a state of a system with energy $E = f(\mathbf{x})$. The probability density of a n dimensional space can be defined as a Gaussian-Markovian system as follows:

$$g(x) = (2\pi T)^{-n/2} \exp[-\Delta x^2/(2T)] \quad (4)$$

where $\Delta x = x_k - x_{(k-1)}$ is the deviation between two solutions at iteration k (Ingber, 1989).

A solution is accepted probabilistically based on the difference in energy, ΔE , between two solutions at temperature T . Specifically, a new solution is accepted based on the probability of obtaining a new state with energy E_k from another state with energy E_{k-1} as follows:

$$\begin{aligned}
 h(\Delta E) &= \frac{\exp(-E_k/T)}{\exp(-E_k/T) + \exp(-E_{(k-1)}/T)} \\
 &= (1 + (\Delta E/T))^{-1} \\
 &\approx \exp(-\Delta E/T)
 \end{aligned} \quad (5)$$

which is the equivalent to Eq. (3), where the sum involves only the current and the new state.

It is important to note that SA can accept worse solutions probabilistically as a function of T ; however, the probability of accepting a worse solution goes to zero as $T \rightarrow 0$. Indeed, the initial temperature is typically set to a high value, then the update function, U , slowly decreases it to zero; thus, the U function effectively controls the exploration and exploitation ability of the algorithm (Fig. 1). Finding the optimal update scheme, U , is not trivial; however, if T is decreasing not faster than $\frac{T_{\text{init}}}{\ln k}$, it is possible to obtain a global optimal solution for a large enough k (Ingber, 1989).

The convergence of the SA can be slow, and therefore many efforts have been made to design versions that improve its speed either by changing the generating function, $N(\mathbf{x})$, or the temperature update function, U . Indeed, it has been shown that SA can work well for any reasonable generating function, $N(\mathbf{x})$, even without requiring ergodicity. Indeed, using the Cauchy distribution as the generating function, SA has been shown to perform better than the classical Gaussian for the Boltzmann distribution (Ingber, 1989).

An alternative approach to speeding up SA is to transform the objective function, such that algorithm can sample from a smoother solution space. Hamacher and Wenzel (1999) proposed a Stochastic Tunneling (STUN) approach; specifically, the objective function, f , is transformed into a cost function, $\hat{f}(\mathbf{x}) = 1 - \exp(-\lambda(f(\mathbf{x}) - f(\mathbf{x}')))$, where $\mathbf{x}'$ is the best solution found and λ is a scaling factor, which is a parameter of the algorithm. $\hat{f}$ smooths the landscape around the local minima and favors jumps into neighboring basins.

Recent advances in quantum computing showed that *Simulated Quantum Annealing* (SQA) outperforms SA on toy problems by requiring only polynomial time whereas the SA still takes exponential time (Crosson and Harrow, 2016).

Fig. 1 Probability of accepting worse solutions as a function of the annealing temperature T . On the x-axis we show the difference in energy between two configurations (ΔE), while the y-axis depicts the probability of accepting a solution.

Genetic Algorithms

Genetic Algorithms (GAs) are bio-inspired optimization methods, which mimic the concept of natural selection. The canonical GA was presented in 1975 by [Holland \(1975\)](#), and later systematically described and analyzed by [Goldberg \(1989\)](#).

In their canonical form, GAs are derivative-free algorithms, as they do not require mathematical information about the objective function. Indeed, GAs use random sampling followed by a selection step based on iterative or probabilistic improvement, which we generally refer to as a evolutionary step.

The central idea of GAs is to use a population of candidate solutions, rather than a single candidate solution as in SA. Let $f: \mathbb{R}^n \rightarrow \mathbb{R}$ be the objective function for an optimization problem; a candidate solution is represented as a vector $\mathbf{x} \in \mathbb{R}^n$, called chromosome, where the i -th variable, $x_i \in \mathbf{x}$, is called a gene. The admissible values of a gene are called alleles; however, while for combinatorial optimization problems this concept is well defined, for continuous optimization problems, it is not. Here, we assume that a solution, $\mathbf{x}$, is a real vector, although GAs can encode solutions in any format; e.g., for the Traveling Salesman Problem (TSP), a chromosome can represent a path over the graph defined by the roads connecting the cities.

To ensure the evolutionary process converges towards good solutions, GAs use a fitness function, F , which assesses the quality of a candidate solution. Obviously, the fitness function can be the objective function, f , itself, or can include additional terms to drive the algorithm towards promising configurations. For example, in the case of constrained optimization, a fitness function, F , can be defined as follows:

$$F(\mathbf{x}) = f(\mathbf{x}) + g(\mathbf{x}) + h(\mathbf{x}) \quad (6)$$

where f is the objective function, but g and h are functions returning a penalty for violating inequality or equality constraints, respectively.

Let F be a fitness function for the optimization problem, f , and a coding scheme for the candidate solutions' GAs evolve a population of candidate solutions as described in [Alg. 2](#).

Algorithm 2: Genetic algorithm (GA)

```

1:    $P \leftarrow \text{Initialize}(m)$ 
2:   Evaluate( $F, P$ )
3:   while  $\neg \text{StoppingCondition}()$  do
4:      $M \leftarrow \text{Select}(P)$ 
5:      $M \leftarrow \text{Recombine}(M)$ 
6:      $M \leftarrow \text{Mutate}(M)$ 
7:     Evaluate( $F, M$ )
8:      $P \leftarrow \text{Replace}(P, M)$ 
9:   return  $P$ 

```

The algorithm starts by creating an initial population, M , of candidate solutions of size m ([Alg. 2](#), line 1), which is a parameter of the algorithm. Typically, the initial population is created at random, but domain-specific information can be introduced to let the algorithm start from promising solutions. In many cases, the initial population is initialized with the best known solution for a problem, often provided by an expert, or its random perturbations. This is a process called seeding, which is often used for engineering problems, where GAs are used to refine the best known solution; however, this operator could affect the behavior of the algorithm, which might work more like a local optimizer than a global one. The size of the population, m , is a key parameter of the algorithm, which affects both the speed and effectiveness of the GA; indeed, a small population makes the algorithm run faster,

but at the cost of increasing the risk of getting trapped in a local minimum. Conversely, a large population size improves the searching ability of the algorithm, at the expense of increased running time. Choosing an optimal population size is not easy, and typically is done empirically.

The GA evaluates the fitness function, F , for the initial population and then starts the evolutionary process. The first step is to select candidate solutions that will form the mating pool, M , picking solutions with the highest fitness value (Alg. 2, line 4). The underlying idea is to mimic the survival-of-the-fittest mechanism observed in Nature, driving the algorithm towards putative optimal solutions. There are many selection schemes reported in literature; here, we address the most commonly used, while a complete review of selection procedures is presented by [Goldberg \(1989\)](#); [Sastry et al. \(2014\)](#).

A classical selection scheme is the roulette-wheel procedure; according to this scheme, each individual in the population is selected probabilistically based on its fitness value, such that better solutions have higher probability of being selected. Thus, for each solution, i , we define a selection probability, $p_i = F_i / \sum_{j=1}^m F_j$, and a cumulative selection probability, $q_i = \sum_{j=1}^i p_j$. Then, the roulette-wheel procedure selects an individual, z , s.t.

$$z = \arg \min_{i=1 \dots m} r \leq q_i \quad (7)$$

with r being a uniform random value in $[0,1]$. The whole procedure is repeated m times to create a new population of m individuals.

An alternative selection strategy is tournament selection, where s solutions are picked at random, with or without replacement, to compete against each other; then, the best among the s solutions is added to the mating pool. A typical value for the size of the tournament is 2. In the case of selection without replacement, the best solution of the population is always selected and the worst is always discarded, while the others are selected probabilistically based on their fitness function value, with probability $p_i > 0$. Indeed, let ρ_i be the rank induced by the fitness of the i -th individual of the population, s.t. $\rho_i = 1$ for the best solution, and $\rho_i = m$ for the worst one. Let the tournament size be $s = 2$, the selection probability of the i -th individual is $p_i = 1 - ((\rho_i - 1) / (m - 1))$. It follows that the best solution has selection probability $p_1 = 1$, the worst has $p_m = 0$, whereas all other individuals have $p_i > 0$. It is possible to use the tournament selection to ensure that the best individual will go into the mating pool, making this an elitist strategy, whereas this is not guaranteed with the roulette wheel.

After m individuals are added to the mating pool, M , they will undergo a recombination, or crossover, step to create new offspring solutions (Alg. 2, line 5). In general, two solutions can undergo a recombination step with probability, $p_c > 0$, otherwise the offspring solutions will be simply a copy of their parents. The recombination probability p_c is a parameter of the GA. The crossover step is typically tailored to a specific optimization problem, however some schemes have been shown to perform consistently well in practice. The simplest recombination operators are the one- and two-point crossovers. Let $\mathbf{u}$ and $\mathbf{v}$ be two solutions of the mating pool, M , with $\mathbf{u} \neq \mathbf{v}$, one point crossover generates two new solutions $\mathbf{x}$, $\mathbf{y}$ such that:

$$\begin{aligned} \mathbf{x} &= [\mathbf{u}[1, \dots, r_p] \mathbf{v}[r_p + 1, \dots, n]] \\ \mathbf{y} &= [\mathbf{v}[1, \dots, r_p] \mathbf{u}[r_p + 1, \dots, n]] \end{aligned} \quad (8)$$

where r_p is the crossover point picked uniformly at random in $[1, n]$. Analogously, let $\mathbf{u}$ and $\mathbf{v}$ be two solutions of the mating pool, M , with $\mathbf{u} \neq \mathbf{v}$; two point crossover generates two new solutions, $\mathbf{x}$ and $\mathbf{y}$, such that:

$$\begin{aligned} \mathbf{x} &= [\mathbf{u}[1, \dots, r_p] \mathbf{v}[r_p + 1, \dots, r_q] \mathbf{u}[r_q + 1, \dots, n]] \\ \mathbf{y} &= [\mathbf{v}[1, \dots, r_p] \mathbf{u}[r_p + 1, \dots, r_q] \mathbf{v}[r_q + 1, \dots, n]] \end{aligned} \quad (9)$$

where r_p, r_q are the two crossover points picked uniformly at random in $[1, n]$ with $r_p \neq r_q$.

An alternative scheme is uniform crossover. Let $\mathbf{u}$ and $\mathbf{v}$ be two solutions in the mating pool, M , with $\mathbf{u} \neq \mathbf{v}$; uniform crossover exchanges the value in $\mathbf{u}[k]$, $\mathbf{v}[k]$ with probability p_s , which is a parameter of the algorithm. While both point and uniform crossover are crucial in generating diversity in the population, and enhancing the exploring ability of the GA, they produce very different offspring solutions; indeed, while point crossover tends to preserve the substructure of the two mating solutions, uniform crossover can potentially destroy any optimal substructure found by the algorithm.

A common problem of crossover operators is the potential flattening of the mating population; indeed, if two solutions have same value at a given position, crossover will keep it unchanged in the offspring. This is problematic since the algorithm may rapidly get stuck in a local optimum. To overcome this problem, GAs use mutation operators; these operators are applied to each solution in the mating pool to add diversity to the population and ensure the entire search space is explored. In general, a mutation operator is applied to each variable of a candidate solution with probability p_m , which is a parameter of the GA (Alg. 2, line 6). p_m is typically set to a low value to ensure that the probability of destroying any optimal substructure is minimized. In general, mutation operators are tailored to the optimization problem ([Bäck et al., 2000](#)). For combinatorial optimization, a typical mutation operator is the random flip operation, where a variable, x_i , is changed at random to another value in its domain; for example, in the case of binary optimization, this reduces to flipping a bit. For continuous optimization problems, mutation operators add a random value to the current value of a variable x_i following a random distribution; a common strategy is to apply a Gaussian noise, $z \sim N(\mu, \sigma)$, where the mean, μ , and standard deviation, σ , are parameters of the GA ([Yao et al., 1999](#)). Mutation operators based on statistical sampling have proven to be extremely effective in evolutionary strategies, where these are the primary search mechanisms. Indeed, [Hansen et al. \(1995\)](#) proposed an evolutionary strategy for continuous global optimization, which uses a multi-variate Gaussian mutation operator, where the mean and covariance matrix are updated at each step to maximize the likelihood of generating better solutions.

Finally, the GA evaluates the fitness of the mating pool (Alg. 2, line 7) and selects the solutions for the next iteration (Alg. 2, line 8). There are different strategies for selecting this population; a common one consists in picking the entire mating pool M as the new population. This strategy assumes that, since the mating pool was filled with the best solutions of the population, the offspring are likely to be better than their parents, somehow mimicking an elitist strategy. An alternative strategy is to replace k old solutions with k solutions from the mating pool; obviously, this procedure is more complex since different replacement strategies can be used (e.g., replace the k worst) and there is an additional parameter, k , to tune. Both strategies are widely used, but the former provides an easier way to preserve promising solutions from one iteration to the other, therefore favoring the convergence towards putative optimal solutions [Sastry et al. \(2014\)](#).

The GA stops when stopping conditions are met; since we do not have mathematical guarantee that the GA has converged to an optimal solution, the stopping criteria are typically heuristic. In general, the algorithm is stopped when a maximum number of iterations or function evaluations is attained, or when the solution is sufficiently close to a predefined objective function value (e.g., least square minimization). An alternative approach would be to stop the GA when the population diversity drops below a certain threshold. A complete overview of stopping criteria is presented in [Aytug and Koehler \(2000\)](#) and [Safe et al. \(2004\)](#).

Closing Remarks

Finding the global optimum of an arbitrary black-box objective function is impossible in polynomial time, and therefore many heuristic deterministic and stochastic methods have been proposed. In this article, we introduced two stochastic algorithms that have been shown to perform consistently well in practice, namely Simulated Annealing (SA) and Genetic Algorithms (GAs).

SA belongs to the family of Monte Carlo sampling methods, which allows to locate putative optimal solutions in extremely rugged objective function landscapes. Interestingly, despite being a stochastic method, statistical physics provides a mathematical guarantee on its convergence. However, years of research have shown that, despite theoretical and engineering efforts to define efficient sampling and cooling schemes for SA, the algorithm still requires a good understanding of the problem to work effectively. These results have decreased the appeal of this method, in favor of new heuristic algorithms that perform well in practice despite limited theoretical foundations.

GAs are stochastic algorithms that iteratively apply sampling procedures and elitism selection strategies to identify putative optimal solutions. In contrast to SA, GAs sample a population of candidate solutions, therefore increasing the probability of identifying a satisfactory solution. Despite limited advances in the analysis of the running time and convergence properties of these methods, GAs are routinely applied with success in many real-world optimization problems, often outperforming deterministic methods. However, similar to SA, GAs are controlled by significant number of parameters, which often require extensive tuning. It is safe to say that, based on recent empirical results, GAs provide a more general optimization framework for global optimization.

Biographical Sketch

Giovanni Stracquadanio is a lecturer in Computer Science and Artificial Intelligence at University of Essex. He is the Head of the Computational Intelligence Lab for Biology and Medicine, which focuses on the development of Computer Aided Design (CAD) methods for genome engineering and data-analysis methods for cancer genomics. He is also the recipient of the Wellcome Trust Seed Award in Science. His research work has been published in prestigious peer-reviewed journals, including *Science*, *Nature Reviews Cancer*, *PNAS* and *Genome Research*.

Panos M. Pardalos serves as distinguished professor of industrial and systems engineering at the University of Florida. Additionally, he is the Paul and Heidi Brown Preeminent Professor of industrial and systems engineering. He is also an affiliated faculty member of the computer and information science Department, the Hellenic Studies Center, and the biomedical engineering program. He is also the director of the Center for Applied Optimization. Pardalos is a world leading expert in global and combinatorial optimization. His recent research interests include network design problems, optimization in telecommunications, e-commerce, data mining, biomedical applications, and massive computing. Pardalos is a fellow of AAAS, INFORMS, and AIMBE. He is the founding editor of several journals, including *Optimization Letters*, the *Journal of Global Optimization*, and *Energy Systems*. In 2013 Pardalos, has been awarded the 2013 EURO Gold Medal prize, bestowed by the Association for European Operational Research Societies. This medal is the preeminent European award given to Operations Research (OR) professionals.

Data Mining in Bioinformatics

Chiara Zucco, University "Magna Graecia" of Catanzaro, Catanzaro, Italy

Introduction

Thanks to the development of technologies capable of carrying out a massive number of tests and, consequently, of acquiring a massive amount of data at once, in recent decades the volume of extracted data related to biological sciences, has significantly increased in terms of complexity, heterogeneity and size. As a consequence, we have witnessed a deep transition of biological sciences that, from mainly driven-by-hypotheses disciplines, have now also become data-driven sciences.

Managing biological data and understanding its underlying correlations, structures and models is one of the main objectives of bioinformatics, an interdisciplinary field encompassing biology, biochemistry, mathematics and information technology and statistics.

Huang *et al.* (2013), define a general workflow for bioinformatics research. Naturally, this process, if necessary, can be cyclical and consists of 4 sub-processes:

- Laboratory collection of experimental data and biological samples.
- Data acquisition by high-throughput omics technologies.
- An analysis of the data is carried out using computational/mathematical/statistical methods.
- Validation of the results with further experimental tests.

The significantly volume's growth of biological data in terms of complexity, heterogeneity and size, constitutes a virtually unlimited potential for information growth but it also poses several challenges. In fact, paradoxically, it becomes increasingly difficult to extract relevant information from the superfluous ones and traditional methods of analysis that solely rely on manual and statistical analysis and domain expert's interpretation result impassable.

Data Mining is a discipline resulting from the combination of classical statistics tools and computer science algorithms, such as machine learning, which allows the extrapolation of knowledge from a large amount of data for the scientific, operational or industrial use of this knowledge.

Background and Fundamentals

Data mining is born as a particular step of a process defined in literature as *Knowledge Discovery in Databases* (KDD). Due to the centrality acquired by Data Mining task within this process, nowadays Data Mining is used as synonym for Knowledge Discovery, also known as Knowledge Discovery and Data Mining.

Using this identification, and reporting Fayyad *et al.* (1996) definition, we can say that Data Mining or KDD is

The non-trivial process of identifying patterns in data that are valid, original, potentially useful and understandable.

Better detailing this definition, it can be said that

Definition 2.1: Knowledge discovery is composed by various steps (*processes*) and has the aim of extracting models or, in general, recurrent structures in data (*patterns*) from data that are:

- *Valid* in the sense that the discovered patterns must occur on new data with a certain degree of certainty,
- *Original*, that is the more the extracted knowledge is not obvious or a priori guessed, the more valuable it is,
- *Potentially useful*, in the sense that it must provide some benefit to the final user or to the following step in the process;
- *Understandable*, i.e., patterns extracted from data must facilitate the understanding of data itself, if not immediately, after a post-processing step.

The search for valid, new, useful and understandable patterns implies that we can define quantitative measures for evaluating patterns, for example estimates of prediction's accuracy on new data, estimates of a suitable defined gain, estimates of complexity of the patterns extracted, etc.

Witten and Frank Witten *et al.* (2016) add to the previous definition that the process should be *automatic* or *semi-automatic*, emphasizing the relationship between Data Mining and Machine Learning.

As shown in Fig. 1, Han *et al.* (2011) synthesize the various steps that characterize the KDD in:

- *Data cleaning*. Given the increasing amount of data that we have said to be heterogeneous, datasets typically present missing data, inconsistent data or data which are susceptible to "noise". A low data quality affects in a negative fashion the information extraction process and, for this reason, as a first step is necessary to remove incomplete or inconsistent data.

Fig. 1 The steps for Data Mining process.

- *Data integration.* This step is necessary if the data come from heterogeneous sources and have to be consistently aggregated.
- *Data selection.* Relevant data are selected.
- *Data transformation.* In this step the data is transformed or consolidated into an appropriate form for the following task. The data can be aggregated, generalized through the use of hierarchies, normalized in a specific range and finally can be integrated new attributes or features, useful for the process of data mining.
- *Data mining.* It consists in the search for models of interest to the user, with subsequent refinements, presented according to defined modes of representation (classification, decision trees, regression, clustering).
- *Pattern evaluation.* Once extracted, the patterns considered valid are selected based on the application of appropriate measures.
- *Knowledge presentation.* The extracted information is presented.

Each step of this process has developed independently from the others, providing a plethora of algorithms. For this reason, a common approach, also useful in bioinformatics environment, involves the modeling of the discovery process through the use of workflows, which help the automation of the process allowing, at the same time, the possibility of testing in parallel different algorithms belonging to the same task of that KDD process.

Data Mining Task

What are the final objectives of KDD? Still in Fayyad's article two categories of objectives are indicated, namely the *Verification* and the *Discovery*. Moreover, the goals for Discovery can be *Prediction* or *Description*. While descriptive discovery aims to find patterns and associations that can be interpreted by the expert of that domain, predictive discovery aims at finding patterns to predict the behavior of other data.

In Data Mining or in the Analysis task, new knowledge – thought as new high-level information expressed in terms of models, association rules, trends or predictions- is extracted from low-level data through approaches deriving from the combination of statistics and computer science tools, such as machine learning.

extraction of high-level information (knowledge) from low-level data (usually stored in large databases) In particular from Machine Learning, Data Mining has derived the distinction between supervised and unsupervised approaches. We briefly describe these techniques with reference to studies in the medical field.

Let suppose to have a set of cases or *instances* and each instance is represented by a set of variables or *attributes*. The first step of supervised learning techniques, is to build a model by training a machine learning algorithm on a set of examples, that are instances containing both input (called features or attributes), and output, consisting in an attribute called *learning target*. The learning algorithm uses these attributes to determine the set of parameters necessary to be able to learn a model that can correctly predict the output. Subsequently, this model is used to predict the unknown target values of new instances.

Two typical examples of supervised learning are *Classification* and *Regression*. If in *Classification* the target attribute is generally nominal and represents the class to which an instance belongs to, the aim of regression is to predict output value of a dependent numerical variable starting from one or more independent features, by inferring a real-valued function.

From this point of view, supervised learning techniques can be used, for example, to define criteria for diagnosis/prognosis or to predict a trend of clinical/vital factors that depend on the clinical subject's data.

Some among the most famous examples of supervised learning algorithms are

- Classification trees,
- Linear classifiers (SVM, Neural Network),
- Rule based classifiers,
- Probabilistic Classifiers (Naive Bayes, Bayesian network, Maximum Entropy).

In *unsupervised learning* structure in data is seek to be found without having examples or labeled outputs, but only relying on similar characteristics to try to make reasonings and forecasts on data and examples of unsupervised learning are, in general, *clustering* and *associative rules*.

In particular, the goal of clustering is to group in sets or *clusters* data that a similar in some way when, unlike classification, these groups are not known a priori. In order to define this similarity, clustering techniques are based on suitable *distance measures*.

Introduced in basket analysis, *associative rules* have found application in many domain, especially in the field known as frequent pattern mining. In fact association rules do not aim to predict values but to search for relationships and dependencies among data. In particular, an association rules can be defined as the relation between two sets of items (i.e., binary attributes) $X \rightarrow Y$ with the meaning that if X occurs, it's likely that Y also occurs.

A major issue of data mining step is to appropriately choose one or a combination of these techniques in order to find a efficiently and reliably solution to a given problem.

In recent years, predictive Data Mining has been widely used in bioinformatics, for example it finds application in genomics and proteomics for: Protein-protein interaction prediction problems (see for example Hood and Friend, 2011; Haider et al., 2015; Nafar and Golshani, 2006; Zhang et al., 2010); protein structure prediction (see Lexa et al., 2009; Fayeche et al., 2013); motif identification in biological data (see Narasimhan et al., 2002; Hoque et al., 2011; Qader and Al-Khafaji, 2014); in gene finding problems it's used in order to identify coding regions of genes etc.

Another important application of Data mining is the discovery of genomic biomarkers for disease discovery or progression, with the aim to obtain a diagnosis that can be more precocious and precise and a prognosis that can lead to more individualized therapies, see Mancilla et al. (2017) -this is for example the perspective of P4-medicine (predictive, personalized, preventive, participatory) Hood and Friend (2011), see also Guzzi et al. (2015).

One important example can be found in the work of Golub et al. (1999), in which is carried out a study focused on the early differential diagnosis of acute myeloid leukemia and acute limbo plastic leukemia.

Nevins et al. (2003) proposed a decision-driven approach to predict patient survival. Predictive data mining approaches have been widely used to predict the outcome in cases of prostate cancer, ovaries, lungs.

More recent examples can be found in the works of Yousefi et al. (2017); Shu et al. (2018); Mobadersany et al. (2018).

Feature Selection

So far, Data Mining process and Machine Learning approaches were presented without any further consideration on dataset dimensions and on the number of attributes in a dataset.

However, it is clear that some variables can be significant for the construction of a model while others maybe not. However, generally speaking, the Data Mining step take into account all the features and this, especially in cases where there are many features, as in bioinformatics, involves problems in terms of accuracy and, also, of performances.

Therefore, it makes sense to ask how to reduce the attributes or features, by selecting only those that are more significant than the others for the construction of a predictive model. Feature selection is the process by which a subset of attributes, regarded as relevant in the construction of a model, is selected.

Feature selection is distinguished by the so-called features reduction techniques, for example based on projection or compression methods, because although both aim to reduce the number of attributes in a dataset, while in the feature selection a subset of attributes is extracted, feature reduction produces a set of combined attributes while previous feature are discarded and this, especially in bioinformatics field, can lead to a loss of information or to interpretation issues.

Dash and Liu (1997), subdivide the feature selection process into 4 phases: *subset generation*, *subset evaluation*, *stopping criterion* and *result validation*.

The first step is based on a search criterion that can be complete, sequential or random. It is necessary to underline that in a n -dimensional feature space, the feature selection methods try to find the best subset, between the 2^n candidate subsets and therefore the problem has exponential complexity with respect to the data dimension.

Several heuristic strategies have been developed to overcome this problem. Guyon et al. (2002) proposed a recursive elimination function (RFE) that performs backward deletion, with the aim of removing the most irrelevant characteristics in a sequential and iterative way, until only a subset of a given dimension remains, according to some stop criteria.

Based on the second step, Yu and Liu (2003) subdivide the feature selection criteria into dependent and independent of the mining algorithm. Among the most common stopping criteria, Yu and Liu (2003) distinguish the following: the search is complete, a bound has been reached (for example a specific number of iterations), the addition or elimination of a feature does not produce a better subset.

The features selection algorithms can be divided into three general categories: *filter methods*, *wrapper methods* and *embedded methods*.

Filter methods select a subset of variables during preprocessing, taking into account only the information content and the intrinsic properties of the data without considering the mining algorithm used. In particular, filter methods apply statistical measures that classify features by assigning a "score" for each of these.

Moreover, these statistical methods are often univariate and consider features independent of one another or in relation to a dependent variable. Some filtering methods are: Pearson Correlation, Mutual Information, Chi Square, Fisher Score.

Wrapper methods consider selecting a subset of features in terms of the following search problem: “What is the subset of features that gives better results based on a chosen learning algorithm?”. So the learning algorithm is used as part of the subset prediction process, in a sort of black box that determines various combinations of the feature set, evaluates them according to the learning algorithm and classifies them in terms of accuracy. The subset that obtains a higher accuracy index is chosen as the final subset. This black box can apply methodological, stochastic or heuristic techniques. In general, wrapper methods are superior to filter methods in terms of performance, but they are slower and computationally more expensive.

In Embedded methods, variable selection takes place as part of the training process, making it more efficient than wrapper methods. Embedded methods incorporate the selection variable within the training process. The most common are the regularization methods. In addition, the CART methods have within them the mechanisms of embedded feature selection.

Data Mining Platforms

This section and, in general, the whole second part of this article, is devoted to give a brief overview of Data Mining and Machine Learning platforms and to introduce programming environments that, at present, are the most used for both bioinformatics and general domain applications.

In particular, in this Section the most popular Data Mining platforms are presented.

WEKA

One of the best known Data Mining software is WEKA, standing for Waikato Environment for Knowledge Analysis and developed by the University of Waikato, in New Zealand, see (Witten *et al.*, 2016; Hall *et al.*, 2009).

It is a free software environment for machine learning written in Java, available for download at: see “Relevant Websites section”.

Weka’s popularity lies in the fact that not only it contains a vast collection of tools for data preprocessing and modeling along with the most used state-of-the-art data mining algorithms, but it also allows an easy access to these functionalities, due to a user-friendly graphical interface that allows the use also for non-expert of Java programming language, in which Weka is written. On the other hand, for Java developers, it is possible to embed Weka algorithm in a Java application.

KNIME

KNIME, standing for Konstanz Information Miner, see Berthold *et al.* (2009), is an open source platform for data analysis, data reporting and integration, data manipulation and visualization, available for download at see “Relevant Websites section”. It integrates libraries of other suites, with an and easy to use interface. KNIME integrates various components of machine learning and data mining through its modular data pipelining concept, and allows data to be added in a workflow. The graphical user interface (GUI) facilitates the assembly of nodes for data pre-processing and the ETL process (Extraction, Transformation, Loading), for modeling, data analysis and visualization. It is written in Java and based on Eclipse and gives the possibility to develop and add plugins that provide additional functionality.

In Gartner’s 2017 magic quadrant (source Linden *et al.*, 2017), KNIME is still indicated as a Leader for data analysis platforms, counting among its strengths the availability of advanced features for data preparation, such as transformation and aggregation, or for feature selection task. A weakness point outlined in the same report is a lower rate of innovation than other leaders.

Rapid Miner

Another leader among the data science platforms that was recently confirmed by Gartner’s magic quadrant is Rapid Miner, see “Relevant Websites section”. RapidMiner, that offers a limited free-version, provides an integrated environment for data science, supporting all phases of the machine learning process, including data preparation, results visualization, model validation and optimization. This along with the user-friendliness and the adaptability, is one the strengths for this tool.

In fact Rapid miner offers different functionalities for different types of users. In particular, the template-based frameworks provide the possibility to develop guided models without the need of coding, and this is useful for user’s that don’t have confidence with programming languages, while for data and computer science experts, it is possible to access advanced analysis tools, for example by embedding algorithms in R and Python scripts. As for KNIME, RapidMiner provides a platform for developers to create data analysis algorithms and share it with other users.

Program Environment for Data Mining

In this section a quick overview of three of the major quantitative software programming languages, MATLAB, Python and R is discussed.

MATLAB

MATLAB (standing for MATrix LABoratory) is a proprietary programming language developed by MathWorks and a multi-paradigm numerical computing environment whose development was initiated by Cleve Moler in the late 1970s, see “Relevant Websites section”.

As the name suggests, MATLAB is one of the easiest-to-use languages when dealing with objects represented as a numeric matrix. Besides that, MATLAB allows the tracing of functions and data, the implementation of algorithms, supporting the interface with programs written in other languages. Popular both among engineering and image processing experts, MATLAB offers a range of program extensions and libraries, called toolboxes, integrated within the main MATLAB interface. This, in addition to the simplicity and power of the matrix manipulation language, is one of the reasons why MathWorks is mentioned as a Challenger in Gartner’s 2017 magic quadrant. A complete description of Matlab is beyond our intentions, so we will focus on the Data Mining Toolbox.

Statistics and Machine Learning Toolbox provides statistical functions and machine learning algorithms for data analysis and modeling. In particular, the toolbox provides descriptive statistics and plots tools and clustering algorithms for performing exploratory data analysis, feature transformation and feature selection algorithms for dimensionality reduction; supervised and unsupervised machine learning algorithms etc.

Among the issues reported by Gartner’s 2017 magic quadrant, one of the biggest is that the as the dataset dimension increases, the analysis performance has a decrease; furthermore, the lack of a visual pipeline makes it less user-friendly than other data science platforms and, therefore, less chosen by non-programmers data scientists. At the same time, data analyst and statisticians tend to prefer open source languages like Python or R.

Python and R

Both Python and R are popular programming languages, used for the development of statistical computing and Machine Learning applications.

While R (see “Relevant Websites section”) was developed in 1995 by Ross Ihaka and Robert Gentleman, [Lafaye de Micheaux et al. \(2013\)](#), as an open source tool with the aim of providing a better and more user-friendly tool for data analysis, statistical and graphics models, Python (see “Relevant Websites section”) is a general purpose programming language developed in late 80’s by Guido van Rossum, see [Zelle \(2004\)](#), with the aim of emphasizing code readability and an easy-to-understand syntax.

R is widely used for the development of statistical software and data analysis algorithms. This for numerous reasons, including:

- As already mentioned, R is designed as a tool to support a statistical analysis or data analysis.
- Being a free and open source development software and having an active development community, R offers a very large number of additional packages, available at the Comprehensive R Archive Network (CRAN) or other repositories such as Bioconductor or GitHub.
- The visualization packages, among all an example is the famous ggplot2, allow to obtain elegant and informative graphics that allow to understand data in a more efficient and effective way.

Notwithstanding these advantages, some issues can be found in the lower user-friendliness of R compared to software providing GUI interface and dealing with graphical workflows for data analysis process. Another weak point can be found in time performances, suffering the comparison with other languages.

Python is also very popular for Data Analysis and Data Mining applications, thanks to its simplicity, the reliability of the written code, the presence of an integrated test framework, the possibility to integrate code inside a notebook, given precisely from Jupyter Notebook for sharing code and material. Moreover, as already mentioned, Python is a general purpose programming language, which allows greater versatility of use.

However, in relation to R, Python suffers the comparison both in Data Visualization, often less elegant than the competitor, and in the number of packages proposed for the Data Analysis.

Data Mining Platforms for Bioinformatics

Ms-Analyzer

MS Analyzer is a tool for the analysis of mass spectrometry proteomics data, see ([Cannataro and Veltri, 2007](#)). One of the major challenge of mass spectrometry proteomics data analysis is the need of a combination of large storage systems, preprocessing techniques, and data mining and visualization tools.

Collection, storage and analysis of huge mass spectra produced in different laboratories can leverage the services of computational grids, that offer efficient data transfer primitives, effective management of large data stores, and large computing power.

The architecture of this tool is formed by two main components, called modules :

- Proteomics data storage system
- Ontology-based workflow editor.

The first module is called SpecDB and implements basic spectra management functions. It divides data in three different repositories:

- Raw spectra repository, or RSR, which stores the raw spectra coming from different experiments and instruments;
- Pre-processed spectra repository, or PSR, which stores the pre-processed spectra;
- Pre-processed and prepared spectra repository (PPSR), which stores spectra that have been pre-processed and are ready to be analyzed by data mining platforms and tools, like Weka.

The ontology-based workflow editor takes advantage of ontologies for modeling Data Mining steps, i.e., preprocessing, data preparation and data analysis tasks, in the view of supporting the design of bioinformatics workflows, which are assumed to be executed in a distributed environment and that every single activity can be performed by invoking both a Web service or another (sub)workflow.

In particular the ontology-based workflow editor is composed by:

1. A dataset manager, that allows to associate to raw spectra, produced by mass spectrometers, with further information, for example related to classes information, and then giving to the user the possibility to choose whether to perform pre-processing, data preparation and/or data analysis;
2. An ontology manager, that allows the user to perform, the browsing, searching and selection of bioinformatics tools. It is based on two ontologies, i.e., ProtOntology for the modeling concept, algorithms and tools related to the proteomic domain and the biological background, and WekaOntology used for the modeling of concept, algorithms and tools that are more related to the Data mining analysis of proteomic data.
3. The graphical Editor, that helps user to graphically design a bioinformatics workflow in UML (Unified modeling language), by dragging and dropping the needed blocks and then associating them one with another.

Dmet-Miner

DMET-Miner, [Agapito et al. \(2015\)](#) is a data mining tool able to extract Association Rules from DMET (Drug Metabolism Enzymes and Transporters) datasets. The Affymetrix DMET microarray platform allows to determine the ADME gene variants of a patient and to correlate them with drug dependency events.

Affymetrix DMET platform enables the simultaneous investigation of all the genes that are related to drug absorption, distribution, metabolism and excretion (ADME).

DMET-Analyzer, [Guzzi et al. \(2012\)](#), is a tool developed in order to perform an automatic association analysis among the variation of the patient genomes and the different patients response to drugs, in the perspective of P4 medicine.

DMET-Analyzer is able to correlate a single variant for each probe, its analysis strategy doesn't allow the discovery of multiple associations among allelic variants.

To bypass these limitations, DMET-Miner tool was developed, that extends the DMET-Analyzer tool performing data mining strategies and correlating the presence of a set of allelic variants with the conditions of patient's samples by exploiting association rules. It uses an efficient data structure and implements an optimized search strategy that reduces the search space and the execution time.

This tool is developed in JAVA and is available under Creative Commons License. It automatically filters useless rows by iteratively applying the Fishers test filter allowing to reduce the search space, improving the performance.

Bioconductor

Bioconductor is an open source and open development software project for computation biology, based on R programming Language see "Relevant Websites section". In particular, Bioconductor works with a high throughput genomic data from DNA sequence, microarray, proteomics, imaging and a number of other data types ([Gentleman et al., 2006](#)).

Following the release policy of R, Bioconductor generally provides two versions per year.

Most of the available packages are software packages performing some analytical calculation. The current available version of Bioconductor (Version 3.6) consists of 1477 software packages.

However, although in smaller numbers, there are also annotation packages (currently around 900) that are similar to databases and are intended to link identifying information (e.g., Affymetrix identifiers, PubMed), with additional information contained in databases such as GenBank, the Gene Ontology, LocusLink etc. Finally, there are also experimental data packages (about 300) and each package generally contains a single data set that can be related or not to some Bioconductor software packages, in order to illustrate particular case studies, or can be related to publications, etc.

Because of its open development nature, particular importance is given to the documentation relating to the packages.

More in details, the Bioconductor policy provides that for each package at least a vignette should be present, i.e., a document in PDF or HTML format that generally includes descriptive text, figures and bibliographic references and also input and output in R that make these vignettes to be easily executable and suitable for an interactive use.

Webmev

Originally developed by The Institute for Genomic Research (TIGR, that merged in 2006 into the J. Craig Venter Institute), the MultiExperiment Viewer (MeV) tool was born as a member of the TM4 suite, an open source suite for the management and analysis of data extracted from microarray experiments, see (Howe *et al.*, 2011). Howe, Sinha, Schlauch, and Quackenbush]. The TM4 suite's goal was to make data analysis more accessible and available for researchers belonging to different fields and consisted of 4 tools:

- The Microarray Data Manager (MADAM), for the management of microarray data through MySQL;
- SpotFinder, for image processing,
- Microarray Data Analysis System (MIDAS) for the normalization and the preprocessing of raw experimental data, in order to create a suitable input for the MeV tool,
- MeV, performing data analysis for the identification of gene expression patterns.

In particular, MeV was developed as a Java based standalone application. Some issue of this approach were related, for example, to the lack of portability and scalability, to the heavy dependence of the application on the computer environment and to the request of downloading datasets on the user's local machine.

For this reasons, a Web Server open-source tool, WebMeV (see "Relevant Websites section") has been recently developed (see Wang *et al.*, 2017), with the aim of taking advantage of modern cloud architectures, relying on a computing server deployed on Amazon Web Service (AWS). Then, through Rserve (an R package that allows to send binary requests to R playing the role of a socket server) the WebMeV application provides advanced analysis methods adapted from Bioconductor packages and related to Normalization, Clustering, Statistics, Meta Analysis.

Conclusions

In this article an introduction Data Mining process has been provided. In particular, Data Mining has been introduced as a central step in the process of Knowledge Discovery in Databases (KDD), with which it is often identified. A brief overview of the KDD steps was then presented, together with the main approaches used in Data Mining, also providing some applications in the bioinformatics field.

In the second part of this article, some of the most known platforms and programming environments related to Data Mining have been presented. Finally, some specific Platforms for Data Mining applications in Bioinformatics were discussed.

Introduction

Knowledge Discovery in Databases (*KDD*) (Fayyad and Uthurusamy, 1996) is an interdisciplinary science whose goal is to extract useful and actionable knowledge from very large data repositories. Mainly, given a data set, a KDD process aims at finding:

- *Classifiers*. A classifier is a decider able to divide data into predefined categories, often called classes.
- *Predictors*. A predictor is a fitting function able to predict a target feature exploiting the remaining data.
- *Clusterings*. A clustering is a process that divides data into unknown categories, called clusters, according to the *similarity* of the data points.
- *Patterns*. A pattern is a discernible regularity within the data, whose elements and/or features repeat in a predictable schema.
- *Anomalies*. An anomaly, often called outlier, is an unexpected piece of information that considerably deviates from the rest of the data.
- *Associations*. An association is a link between two or more phenomena, coded in pieces of information.
- *Models*. A model is a mathematical and/or logic sets of functions able to describe data distributions and behaviors.

In the last decades, KDD has proven to be an essential element of our research, economy and society due to the increasing availability of data in private, public and web databases. The application fields are vast and space in different domains, for instance:

- *Healthcare*. In the last decades, KDD was successfully used to improve several medical aspects: (i) The health system management, by identifying best practices, optimizing processes and reducing costs; (ii) the fraud and abuse detection; (iii) the disease recognition; (iv) the treatment decision making.
- *Market*. KDD is massively exploited in Business and Market analysis. The main objective is to find a model able to fit user segments and their interests in order to discover which products or services are the most likely to be bought, allowing the retailer to understand the buyer's purchase behavior.
- *Cyber Security*. Any activity that compromises the integrity and confidentiality of an information is a security threat. The defensive measures to prevent a data breach includes different procedures, that are currently benefiting from KDD applications, like: intrusion detection, access control, user profiling, malware discovery, anomaly detection.
- *Bioinformatics*. As a relatively recent research field, Bioinformatics leaves large space to research activities and it is rich of large data repositories, gathered in biology and in related life sciences areas. These data are actually analyzed via KDD procedures to try to give answers to different problems, e.g., gene identification, protein and gene interaction network reconstruction, protein function inference, disease diagnosis, prognosis and treatment optimization.

Focusing on biomedicine and bioinformatics, typically data exhibit strong complexities (Dugas *et al.*, 2002; Akil *et al.*, 2011; Holzinger, 2012, 2014) making manual analysis hard or even impossible: a big current challenge, in clinical practice and biomedical research is, hence, the information overload (Berghel, 1997; Noone *et al.*, 1998), i.e., the phenomenon which prevents a decision maker from taking any decision or action dealing with a target issue that produces too much information to analyze.

What is a KDD Process?

Summarizing and formalizing what we said in Section "Introduction", we can state that a KDD process is an activity of (semi-) automatic discovery of knowledge, models, patterns and anomalies in large data repositories. Knowledge is the understanding of the phenomenon that produces the observed data; models are mathematical and logic sets of functions describing the data and explaining their behavior; patterns and anomalies are respectively expected regularities and abnormal observations within the data.

The discovered knowledge should have the following properties:

- *Novelty*. The worthiness of a KDD process depends on which knowledge is discovered. An unknown piece of information has a big value in improving a decision making action, while a trivial information is worthless: *the more unexpected it is, the bigger its value*.
- *Utility*. The discovered knowledge should be useful in supporting the decision making process through suggesting possible and sustainable actions.
- *Generality*. The results of a KDD process, related to a target phenomenon, should be used in a repeatable manner when facing similar phenomena. This concept should be applicable also when considering the same phenomenon during time, unless the structure of the phenomenon has been changed.
- *Understandability*. The results of a KDD process should be clear and easy to read by non-expert users. However, there are many real applications that require that even the intermediate steps of the KDD process have to be intelligible by humans.

Why KDD in Medical and Biological Sciences?

Medicine, life science, biology and health care are sciences that span from the microscopic world (atoms, molecules, viruses, bacteria, cells, tissues) to the macroscopic one (organs, patients, population, health care processes) (Holzinger, 2012). The quantity of data they are able to collect is enormous and heterogeneous. Holzinger *et al.* (2014) propose a simple example for giving an order of magnitude: the omics world (e.g., genomics, proteomics, transcriptomics, microbiomics, etc.) produces many Terabytes (1 Tera Byte = 1000 Giga Bytes = 10^{12} Bytes) of genomics data for each individual, while merging, for instance, these data with the proteomics produces Exabytes of data (1 ExaByte = 1,000,000 Tera Byte = 10^{18} Bytes); things exacerbates when involving other kinds of information such as texts in natural language describing patients' status, laboratory and physiological sensor data, health care management processes, medical and biological research data.

Health sciences have always been data intensive (Ranganathan *et al.*, 2011; Kolker *et al.*, 2014), but their size and complexity are constantly growing up, providing future scenarios rich of possibilities. However there are some practical challenges to deal with when trying to get actionable knowledge from these data: heterogeneity, noise, inconsistency and missing information are typical issues (Kim *et al.*, 2003).

For these reasons, all the health sciences are moving towards the knowledge discovery research area trying to borrow or define methodologies, techniques and best practices to address their complex analytical problems. In Section "KDD Examples in Health Sciences" we will provide some examples where KDD helped in this direction.

How to Perform a KDD Process?

Currently, there is no dominant standard methodology for developing a KDD process. One of the most used approach is the Cross Industry Standard Process for Data Mining (CRISP-DM) Chapman *et al.* (2000). CRISP. It is a 6-phase model that describe a widely set of KDD problems:

1. Business understanding,
2. Data understanding,
3. Data preparation,
4. Modeling,
5. Evaluation,
6. Deployment.

The particularity of this methodology is the life cycle: at each phase, if necessary, the process can restart from any of the previous phases.

Business Understanding

The objective of this phase is to determine the business objectives by defining which are the business success criteria. The first step is to make a situation assessment, performing the resource inventory, analyzing the requirements, the assumptions and the constraints of the business activity, and drawing up a cost and benefit report. Once the initial setting is clear, the *Data Mining* goals and criteria must be defined, in other words we have to choose what we expect from the data analysis and how we can judge if the goals were reached. Finally, we have to produce a project plan stating all the objectives and the initial assessment of required resources, tools and techniques.

Data Understanding

The next phase is aiming at becoming acquainted with the available data. Typically, data are stored in different repositories with different structures; for this reason we need to start an initial data collection from all the data sources. Data are characterized by distributions that can be observed by *exploratory analysis* (Tukey, 1977), which is an approach for data analysis that employs a variety of techniques (mostly graphical) in order to build an overview about data insights, discover underlying structures, define important variables and detect anomalies. Some of the typical tools for exploratory data analysis (Chambers *et al.*, 1983) are: charts, graphs, data traces, histograms, probability plots, lag plots, scatter plots, Youden plots, deviation plots and box plots. The final objective of this phase is to verify the quality of the available data in order to understand if mining and business goals are achievable.

Data Preparation

Raw data must be manipulated (Rahm and Do, 2000) to be successfully analyzed. First of all we have to select the portion of the information that allows to reach the mining goals, from the different data sources: usually, data repositories contain much more data than necessary. Then, procedures of data cleaning are very common; this procedures aim at improving the data quality and readability by:

1. Identifying and dealing with outliers,
2. Smoothing out noisy data,

3. Filling in missing values,
4. Correcting inconsistent data,
5. Removing irrelevant/redundant data, in terms of features and samples.

Enriching data with new information could help in a deeper and fruitful data insight understanding. A common practice, at this stage, is the creation of new attributes and data features. General methodologies of new feature creations are:

1. Feature extraction: exploitation of domain-specific knowledge,
2. Mapping data to new space: algebraic transformations that allow a data domain change to better understand their behavior,
3. Aggregation: computing statistical operations over a subset of data,
4. Feature construction: combining two or more features,
5. Data transformation: applying mathematical functions to a subset of features.

Modeling

Prepared data are exploited to feed *Data Mining Models* (Witten and Frank, 2005), whose objective is to find the desired knowledge. At this stage the analyst has to choose which techniques better fit the data in order to achieve the target goals. A *Model Building Design* must be defined, which is a workflow that govern the model generation process and its parameter configuration. This workflow can be a complex graph composed by (parallel) cascades of different models linked like chains and combined at the end of the process.

Literature provides a vast selection of mining techniques able to solve different kind of problems, which are typically:

- *Classification*. It is the problem of identifying the belonging class of a new observation. Classes are a priori known and are characterized by the features of the data they contain. Some common classification techniques are: Naïve Bayes (Zhang, 2004), Bayesian Networks (Friedman *et al.*, 1997), Logistic Regression (Collins *et al.*, 2002), (Deep) Neural Networks (Haykin, 1998; Goodfellow *et al.*, 2016), Support Vector Machines (Steinwart and Christmann, 2008), KNN (Cover and Hart, 2006), Ripper (Cohen, 1995), PART (Frank and Witten, 1998), Decision Trees (Quinlan, 1986), Random Forest (Breiman, 2001).
- *Regression*. Regression is a statistical processes for estimating the relationships among numerical variables. Given a classical data generation function f , such that $\vec{y} = f(\vec{x}, \vec{\theta})$, where y is the output, $\vec{x}$ the input and $\vec{\theta}$ the function parameters, the objective of the regression is to make some assumption about the nature of f and estimate $\vec{\theta}$ only by observing $\vec{y}$ and $\vec{x}$. Some examples of regression are: Linear Regression (Yan and Su, 2009), Multi Linear Regression (Rao *et al.*, 2008) and Ridge Regression (Hoerl and Kennard, 2000).
- *Clustering*. Clustering is a similar but more complex task than Classification. The objective is the same, find the belonging classes (categories) of new observations; the difference consists in the missing knowledge about the classes: categories, their number and their characteristics are unknown. For these reasons, clustering techniques aim at grouping together the data points into clusters, according to some similarity statistics or distance: points that are similar or close should lie in same cluster, while different or distant points should belong to different clusters. Well-known algorithms in this field are: K-Means (Hartigan and Wong, 1979), K-Medoids (Li, 2009), BD-Scan (Ester *et al.*, 1996), Expectation Maximization (Dempster *et al.*, 1977).
- *Association Mining*. The objective of this research area is to find, within a data set, associations between data points or data point types that recur with a statistical significance. In other words, we are wondering if there are some elements in the data that appear together with high frequency. The best known algorithms for finding associations are Apriori (Agrawal and Srikant, 1994) and FP-Growth (Han *et al.*, 2000).
- *Anomaly detection*. Anomaly detection is the identification of items, events or observations which exhibit a strong difference in behavior from the expectation. Typically, data sources are governed by a set of unknown (or hard to be managed) generative processes that can explain the observed phenomena. These processes can be modeled as mathematical distributions (mixture of components) that generate data points. Each distribution is likely to represent a pattern, that is characterized by an expectation and a deviation. However, errors, noise or abnormal events can generate rare data points that do not follow the pattern schema, turning out to be anomalies different from the remaining ("normal") data points, due to an excessive deviation. Finding these points, called outliers, is the objective of the anomaly detection.

Anomaly detection techniques can be divided into two categories:

- Unbalanced classification: given a dataset whose outliers are known, it is possible to define a classification problem whose classes are "is_outlier" and "is_not_outlier", obviously the former has a much smaller size than the latter,
- Deviance from clusters: when outliers are unknown, a reasonable procedure is to find clusters and mark as anomalies all those points that deviate beyond a chosen threshold from the expectation of each cluster.

Popular algorithms are: BD-Scan (Ester *et al.*, 1996), Isolation Forest (Liu *et al.*, 2008) and CBOD (Jiang and An, 2008).

Evaluation

The Mining Workflow is able to produce results that have to be evaluated in order to understand if they match the Mining goals. A simple evaluation protocol, shown in Fig. 1, is described as follows:

Fig. 1 Simple evaluation workflow.

- From the data sources three datasets are produced: Training set, Validation set and Test set,
- The Training set is provided to an Inference Algorithm whose objective is to build the Mining Model,
- The validation set will help the Inference Algorithm in finding the best algorithm's parameter set trying to avoid configuration of poor quality. Usually, the Validation Set is exploited to compute quality measures during the model building phase and to determine if the algorithm meets its stopping criterion,
- The Evaluation module will apply the Mining Model to the Test Set to generate the final statistics for judging the model quality.

It is important to notice that the sets of data, exploited to compute statistical measures (Test and Validation sets), should be different and independent from the Training Set, for ensuring the fairness of the statistical evaluation.

The evaluation metrics (very often graphical), that better fit business objectives, differ according to the mining goals (Witten and Frank, 2005). For instance, when dealing with classifiers, typical measures are: Confusion matrix, Precision, Recall, F-Measure, Cost, ROC analysis; while for clustering tasks some useful metrics are: Davies-Bouldin index, Dunn index and Silhouette coefficient.

Deployment

When the evaluation phase certifies that the mining goals are achieved, the final step of the CRISP-DM Methodology is the *Model Workflow Deployment*. This is a very crucial step, since in most cases, the end-user is not a data analyst, but the person who commissioned the entire KDD process to the data analysts: a clear and practical documentation is strongly recommended.

The deployment phase must match the business requirements and can range from simple process reports, to lists of useful insights, to complex implementations of the entire mining workflow.

KDD Examples in Health Sciences

One of the first examples of a knowledge discovery process in medical diagnostics is in Reeder and Felson (1977) where authors collected a big list of clinical differential diagnoses in radiology. The drawback here is that the data analysis process was manually performed, limiting the quantity of data that could be analyzed.

Nowadays, (semi-)automatic KDD processes are massively exploited in health sciences under many different perspectives such as semantic data annotation, genomics, protein structure modeling and biological system evolution (Brusic and Zeleznikow, 1999).

Wang *et al.* (2018) propose a recommender system (a cross among association and prediction) able to predict drug-gene-disease associations, breaking the traditional paradigm of "one-drug-one-gene-one-disease", which is not able to tackle diseases involving multiple malfunctioning genes. Thank to this novel technique, Wang *et al.* were able to discover that the diazoxide drug can inhibit malfunctions in multiple kinase genes, leading towards another step to develop a targeted therapy against breast cancer.

In (Wang *et al.*, 2017), KDD and electronic medical records were exploited to improve the hospital treatment quality and increase the patient survival rate. Wang *et al.* defined a convolutional neural networks, fed by patient vital signs and hospitalization history as time series, for the readmission prediction, a well-know problem in literature. An early readmission corresponds to the possibility of an early intervention, preventing dangerous events and reducing healthcare costs.

Monteiro *et al.* (2017) propose machine learning techniques and feature enrichment to improve the prediction of the functional outcome of ischemic stroke patients after three months from the emergency treatment. The motivation of this work lies in the fact that the prognosis is strongly correlated with the early stages of the treatment during the acute phase when a stroke occur.

The last example, we highlight, was proposed by Alhusain and Hafez (2017). They adapted the well-known prediction algorithm Random Forest (Breiman, 2001), to a clustering setting. The objective was to detect interesting patterns in genetic data in

order to address population structure analysis problem, aimed at finding genetic subpopulations based on shared genetic variations of individuals in a population.

Closing Remarks

In this discussion we gave an overview about the Knowledge Discovery in Database science. A general definition of KDD was provided, describing it as an effective set of methodologies, techniques and tools for data analysis aimed at unearthing useful knowledge buried within large amounts of information. We explored the principal KDD's areas, categorizing them according to their capabilities and objectives. A well-known methodology, for managing KDD processes, was presented, namely CRISP-DM. Each phase of this methodology has been discussed and enriched with definitions and bibliographic references for further and deeper readings, hoping to have intrigued the reader for continuing to study this fascinating discipline.

Introduction

In the field of machine learning (ML) it is possible to distinguish two fundamental categories: supervised learning and unsupervised learning techniques. The main aim of the former category is the search for algorithms that reason from externally supplied observations (also called training instances) to produce general hypotheses, which then make predictions about future instances (Kotsiantis *et al.*, 2007). One important area of supervised machine learning relates to classification problems, a task that is usually performed in a supervised setting. Given k possible class labels, a training set of pairs (x_i, y_i) with $x_i \in \mathbb{X}^M$ denoting a training instance described by M features and $y_i \in 1, \dots, k$ representing the correct class label for the observation x_i , the objective of classification is to build a model of the distribution of class labels in terms of predictor features. The resulting classifier is then used to assign class labels to the testing instances (also called unseen instances) where the values of the predictor features are known, but the value of the class label is unknown. According to the number of possible labels, it is possible to distinguish binary classification problems and multi-class classification problems. In the former case, only two class labels exist, while in the latter the number of class labels is greater than 2. The aim of this article is to introduce the reader to supervised machine learning methods for classification. In particular, Section “Classification problems in Bioinformatics” reports some of the most important challenges in the field of Bioinformatics that can be solved as classification problems. Subsequently, Section “Methods” presents some of the existing supervised methods used to address a classification task, while Section “Performance Evaluation” presents measures that are commonly employed to evaluate the performance of a classifier. Section “Current research and Open Issues” outlines some recent advances and challenges in the area of supervised learning for classification problems, while Section “Conclusions” summarizes the main concepts presented in the article, suggesting further documents for more advanced concepts.

Classification Problems in Bioinformatics

Classification is a fundamental task in Bioinformatics, and a plethora of work using ML techniques to address the classification task has been proposed. While a complete review of the existing works is beyond the scope of this article, this section reports the main application of supervised machine learning techniques to address classification problems in the field of Bioinformatics.

The most known application of classification methods related to microarray data. In Díaz-Uriarte and Alvarez de Andrés (2006), authors propose the use of random forest (Breiman, 2001) for the classification of microarray data. In detail, authors investigate the use of random forest for classification of microarray data (including multi-class problems) and propose a new method of gene selection in classification problems based on random forest. Using simulated and nine microarray data sets they show that random forest has comparable performance to other classification methods and that the proposed gene selection procedure yields very small sets of genes (smaller than alternative methods) while preserving predictive accuracy.

In Furey *et al.* (2000), authors have developed a method to analyze microarray data using support vector machines (SVMs). This analysis consists of both classification of the tissue samples and an exploration of the data for mislabelled or questionable tissue results. The method is tested on samples consisting of ovarian cancer tissues, normal ovarian tissues, and other normal tissues. As a result of computational analysis, a tissue sample is discovered and confirmed to be wrongly labeled. To show the robustness of the SVM method, authors analyzed two previously published datasets from other types of tissues or cells, achieving comparable results.

An extensive comparison of classification tools applied to microarray data is presented in Lee *et al.* (2005). In this paper, authors evaluate the performance of different classification methods in microarray experiment, and provide the guidelines for finding the most appropriate classification tools in various situations. The comparison considers different combinations of classification methods, datasets and gene selection techniques. Among the different classification methods, there are random forest, classification and regression tree (CART) (Breiman *et al.*, 1984), bagging (Quinlan *et al.*, 1996), boosting (Quinlan *et al.*, 1996), SVMs and artificial neural networks (ANNs) (Patterson, 1998). The comparison study shows several interesting facts, providing some insights into the classification tools in microarray data analysis. In particular, the study shows that aggregating classifiers such as bagging, boosting and random forest improve the performance of CART significantly, being random forest the most excellent method among the tree methods when the number of classes is moderate. The experimental study also shows that SVM gives the best performance among the machine learning methods in most datasets regardless of the gene selection.

A review of other studies where supervised ML methods have been applied to the classification of genomic data can be found in Díaz-Uriarte (2005).

Other applications of supervised ML classification techniques in Bioinformatics include the identification of splice site (Zhang *et al.*, 2006), classification of proteins according to their function (Ding and Dubchak, 2001), the prediction of nucleosome positioning from primary DNA sequence (Peckham *et al.*, 2007), mass spectrometry analysis (Sauer *et al.*, 2008), classification of human genomic regions (Yip *et al.*, 2012).

Methods

This section is dedicated to the description of the most popular and used classification techniques. Specifically, the following techniques are outlined: decision trees, random forest, bagging and boosting, support vector machines, artificial neural networks. While the list does not cover all the existing methods, the presented techniques are by far the ones that are widely used in the Bioinformatics field. The interested reader can find additional information in the reference work of [Duda et al. \(2012\)](#).

Decision Tree

As reported in [Murthy \(1998\)](#), decision trees are a way to represent rules underlying data with hierarchical, sequential structures that recursively partition the data. Decision tree learning is used to approximate discrete-valued target functions, in which the learned function is represented by a decision tree. Learned trees can also be re-represented as sets of if-then rules to improve human readability ([Michalski et al., 2013](#)).

In particular, a decision tree for a classification problem can be represented in the form of a tree structure, where each node of the tree can be a leaf node or a decision node. A leaf node indicates the value of the target attribute (class), while a decision node specifies some test to be performed on a single feature of the available observation, with one branch for each possible outcome of the test. The process of classifying a given instance by means of a decision tree starts by evaluating of the test contained in the root node (a decision node) and moving through it until a leaf node, which provides the classification of the instance.

The most commonly used algorithm to build decision trees is the C4.5 proposed in [Quinlan \(1993\)](#) as an extension of the ID3 algorithm proposed in [Quinlan \(1993\)](#). The tree is constructed in a top-down recursive divide-and-conquer manner. At start, all the training examples are at the root and the attributes (features) are categorical (if continuous-valued, they are discretized in advance). Subsequently, samples are partitioned recursively based on selected attributes. After the partitioning step, test attributes are selected on the basis of a heuristic or statistical measure (e.g., information gain [Michalski et al. \(2013\)](#)). The algorithm ends when one of the following termination conditions holds: all samples for a given node belong to the same class, there are no remaining attributes for further partitioning, there are no samples left.

The pseudocode of the algorithm DecisionTreeBuilding (S, A) is the following, where S is the set of training instances and A the list of features:

1. Create a node N ;
2. If all samples belong to the same class C then label N with C and terminate;
3. If A is empty then label N with the most common class C in S (majority voting) and terminate;
4. Select $a \in A$, with the highest information gain and label N with a ;
5. For each value v of a :
 - (a) Grow a branch from N with condition $a=v$;
 - (b) Let S_v be the subset of instances in S with $a=v$;
 - (c) If S_v is empty then attach a leaf labeled with the most common class in S , else attach the node generated by DecisionTreeBuilding ($S_v, A - a$).

A decision tree can be used for data exploration to achieve the following objectives: (1) to reduce a volume of data by transforming it into a more compact form which preserves the essential characteristics and provides an accurate summary; (2) to discover whether the data contains well-separated classes of objects, such that the classes can be interpreted meaningfully in the context of a substantive theory; (3) to uncover a mapping from independent to dependent variables that is useful for predicting the value of the dependent variable in the future.

While decision trees are able to generate human-understandable rules without requiring much computational effort, they present some disadvantages. In particular, as reported in [Michalski et al. \(2013\)](#), practical issues in learning decision trees include handling continuous attributes, choosing an appropriate attribute selection measure, handling training data with missing attribute values, handling attributes with differing costs, avoiding overfitting of the learned model (i.e., model that is overspecialised on training instances).

Bagging and Boosting

Bagging and Boosting ([Quinlan et al., 1996](#)) are ensemble techniques that combine several machine learning methods into one predictive model in order to decrease the variance (bagging) or the bias (boosting). Both of them consist of the following steps: (1) producing a distribution of simple ML models on subsets of the original data; (2) combining the distribution into one "aggregated" model.

Bagging (whose name stands for Bootstrap Aggregating) starts by creating random samples of the training data set (using combinations with repetitions to produce multisets of the same cardinality of the original data). Then, it builds a classifier for each sample and, finally, results of these multiple classifiers are combined using average or majority voting. Bagging builds each model independently and, for this reason, it is considered as a parallel ensemble method. By increasing the size of the training set (i.e., considering different samples of the same cardinality) bagging decreases the variance of the final model,

tuning the prediction to the expected outcome (Bauer and Kohavi, 1999). As such, bagging is particularly useful when a model overfits the training instances. An example of bagging that makes use of tree models is represented by random forests (Breiman, 2001).

On the other, boosting is based on a two-step approach, where one first uses subsets of the original data to produce a series of averagely performing models and then “boosts” their performance by combining them together using a particular cost function (majority vote). Unlike bagging, in the classical boosting the subset creation is not random and depends upon the performance of the previous models: every new subset contains the elements that were (likely to be) misclassified by previous models (Bauer and Kohavi, 1999). Hence, differently from bagging, boosting provides sequential learning of the models, where the first model is learned on the whole data set, while the following are learned on the training set based on the performance of the previous one. More in detail, it starts by classifying original data set and giving equal weights to each observation. If classes are predicted incorrectly using the first learner, then it gives higher weight to the missed classified observation. Being an iterative process, it continues to add classifier learner until a limit is reached in the number of models or accuracy. Boosting has shown better predictive accuracy than bagging, but it also tends to overfit the training data. An example of this ensemble method is the AdaBoost algorithm (Rätsch *et al.*, 2001).

Random Forest

Random forest (Breiman, 2001) is an ensemble approach that can be used to perform both classification and regression tasks. The main principle behind ensemble methods is that a group of weak learners can be joined to form a strong learner. That is, ensemble methods use multiple learning algorithms to obtain better predictive performance than could be obtained from any of the constituent learning algorithms alone.

As reported in Breiman (2001), random forests are a combination of tree predictors (i.e., a decision tree which, in ensemble terms, corresponds to the weak learner) such that each tree depends on the values of a random vector sampled independently and with the same distribution for all trees in the forest. Hence, random forest adds an additional level of randomness with respect to bagging. More in detail, in addition to constructing each tree using a different bootstrap sample of the data, random forests change how the classification trees are constructed. While in standard trees each node is split using the best split among all variables, in a random forest each node is split using the best among a subset of predictors randomly chosen at that node (Liaw and Wiener, 2002). While this strategy looks counterintuitive, it turns out to perform very well compared to many other classifiers and is robust against overfitting (Breiman, 2001).

Given N training samples and M variables and being B the number of decision trees in the forest, each one of the B trees is constructed as follows:

1. Choose a training set for this tree by choosing n times with replacement from all N available training cases (i.e., take a bootstrap sample). Use the rest of the cases to estimate the error of the tree, by predicting their classes;
2. For each node of the tree, randomly choose m variables (m should be much less than M) on which to base the decision at that node. Calculate the best split based on these m variables in the training set;
3. Each tree is fully grown and not pruned (as may be done in constructing a normal decision tree classifier).

Hence, the only difference with respect to bagging is that instead of using all the M variables in a decision node, only a small subset of them is considered to calculate the best split of the data. When a new instance is entered into the model, it is run down all of the trees. For prediction, a new sample is pushed down all the trees and the result (the class label for the instance), is obtained by means of a voting majority that considers the output of all the weak learners.

While random forests only require specifying two parameters (the number of variables in the random subset at each node and the number of trees in the forest) and the performance they achieved is usually not very sensitive to their values, they still present some disadvantages. In particular, the final model consists of a set of decision trees and it is not easy to interpret for a human-being. That is, random forest is a predictive modeling tool, not a descriptive tool. Hence, if a description of the relationships existing in the available data is fundamental, random forests are not a viable option to be considered.

Support Vector Machine

Support Vector Machines (Vapnik and Vapnik, 1998) are a set of supervised learning methods used for classification and regression. In the case of a classification task, given a set of data points in a n -dimensional space, each belonging to one of the possible classes, SVM aims at finding the separating hyperplanes that maximize the margin between sets of data. This should ensure a good generalization ability of the method, under the hypothesis of consistent target function between training and testing data. To calculate the margin between data belonging to two different classes (i.e., binary classification task), two parallel hyperplanes are constructed (one on each side of the separating hyperplane) and “pushed up against” the two data sets. Intuitively, a good separation is achieved by the hyperplane that has the largest distance to the neighbouring data points of both classes, since in general the larger the margin the lower the generalization error of the classifier. The parameters of the maximum-margin hyperplane are derived by solving large quadratic programming (QP) optimization problems. As reported in

Vapnik and Vapnik (1998), there exist several specialized algorithms for quickly solving these problems that arise from SVMs, mostly reliant on heuristics for breaking the problem down into smaller, more manageable chunks (Platt, 1999).

While the original problem may be stated in a finite dimensional space, it often happens that in the original n -dimensional space the sets to be discriminated are not linearly separable. In this case, the original finite dimensional space is mapped into a much higher-dimensional space, in the hope that in this new space the data could become more easily separated or better structured. To achieve this, SVMs use a mapping into a larger space by means of a kernel function (Hofmann *et al.*, 2008) $K(x, y) = \langle f(x), f(y) \rangle$. Here K is the kernel function, x, y are n -dimensional inputs. f is a map from n -dimensional to m -dimensional space and $\langle x, y \rangle$ denotes the dot product. Usually, m is much larger than n . This mapping function, however, does not need to be computed because of a tool called the kernel trick: the idea is to define K in terms of original space itself without even defining what the transformation function f is (Hofmann *et al.*, 2008).

Artificial Neural Networks

Artificial neural networks were initially developed according to the observation that biological learning systems are built of very complex webs of interconnected neurons. While a large variety of networks have been proposed in the literature (Haykin and Network, 2004) the main structure shared by the different models is the one in which the network is composed of units (also called neurons), and connections between them, which together determine the behaviour of the network. The choice of the network type depends on the problem to be solved; the backpropagation gradient network is the most frequently used (Hecht-Nielsen *et al.*, 1988). As described in Reby *et al.* (1997), this network consists of three or more neuron layers: one input layer, one output layer, and at least one hidden layer. In most cases, a network with only one hidden layer is used to restrict calculation time, especially when the results obtained are satisfactory. All the neurons of each layer (except the neurons of the last one) are connected by an axon to each neuron of the next layer.

The back propagation algorithm is commonly used for training artificial neural networks (Haykin and Network, 2004). The training is usually performed by an iterative updating of the weights based on the error signal. This error is calculated, in the output layer, as the difference between the true class and the actual output values, multiplied by the slope of a sigmoidal activation function. Then the error signal is back-propagated to the lower layers. Under this light, back propagation is a descent algorithm, which attempts to minimize the error at each iteration. The weights of the network are adjusted by the learning algorithm such that the error is decreased along a descent direction. Traditionally, two parameters, called learning rate and momentum factor, are used for controlling the weight adjustment along the descent direction and for dampening oscillations (Hecht-Nielsen *et al.*, 1988). The training of a network with the back propagation algorithm can be summarized as follows:

1. Initialize the input weights for all neurons to some random numbers between 0 and 1;
2. Apply input to the network (i.e., provide one training instance to the network);
3. Calculate the output;
4. Compare the resulting output with the desired one (target class label) for the given input;
5. Modify the weights and threshold for all neurons using the error;
6. Repeat the process until the error reaches an acceptable value (e.g., accuracy is greater than a given threshold).

For all the details related to the back propagation algorithm and for a complete review of the existing networks, the reader is referred to Haykin and Network (2004).

ANNs have been used to perform both binary (Zhang, 2000) neural and multi-class classification (Ou and Murphey, 2007). In particular, Ou and Murphey (2007) presented an in-depth study on multi-class pattern classification using neural networks. Specifically, they discussed two different architectures, systems of multiple neural networks and single neural network systems, and three types of modeling approaches. The study shows that these different systems have their own strength over different application problems along the directions of system generalization within feature space, incremental class learning, learning from imbalanced data, large number of pattern classes, and small and large training data.

A complete guide to the design of ANNs to address classification problems can be found in Demuth *et al.* (2014), where the aforementioned issues are discussed.

Performance Evaluation

Once one of the existing techniques is selected to build a classifier, it is fundamental to evaluate its performance. Several measures have been defined to evaluate the performance of a classifier and this section presents the ones that are commonly used.

The discussion starts by considering binary classification problems and the related performance measures. After this presentation, measures used to evaluate multi-class classifiers are presented.

In a binary classification problem, each observation belongs to one element of the set $\{p, n\}$, where p denotes the positive class and n denotes the negative class. In this scenario, given a classifier and an instance, there are four possible outcomes. If the instance is positive and it is classified as positive, it is counted as a true positive (TP); if it is classified as negative, it is counted as a false negative (FN). If the instance is negative and it is classified as negative, it is counted as a true negative (TN); if it is classified as

Table 1 Confusion matrix. Across the top are the true class labels and down the side are the predicted class labels. Each cell contains the number of predictions made by the classifier that fall into that cell

		True class	
		p	n
Predicted class	p	True Positives	False Positives
	n	False Negatives	True Negatives

positive, it is counted as a false positive (FP) (Fawcett, 2006). Given a classifier and a set of observations, it is possible to build a two-by-two confusion matrix representing the dispositions of the set of instances. Table 1 represents a confusion matrix. Across the top are the true class labels and down the side are the predicted class labels. Each cell contains the number of predictions made by the classifier that fall into that cell.

Based on the information reported in the confusion matrix it is possible to derive the most often used measures for binary classification performance evaluation. More in detail, the numbers along the major diagonal of the confusion matrix represent the correct decisions made.

The measure that is commonly used is accuracy. Accuracy is defined as the number of correct predictions made divided by the total number of predictions made. Hence, $Accuracy = \frac{TP+TN}{TP+TN+FN+FP}$. Hence, accuracy represents the overall effectiveness of a classifier. Anyway, only considering the accuracy as a performance measure can lead to some misleading interpretation about the classifier. This is the case of a dataset that is very unbalanced (i.e., the observations belonging to one class are much more than the ones belonging to the second class). Considering a dataset where the 90% of the instances belongs to the class p , a classifier that classifies all the instances (also the one belonging to the class n) as belonging to class p reaches a 90% of accuracy, even though such a classifier is useless. To avoid this issue, other measures are also considered.

Precision is defined as the number of true positives divided by the number of true positives and false positives. Thus, $Precision = \frac{TP}{TP+FP}$. In other words, it is the number of positive predictions divided by the total number of positive class values predicted. Precision represents class agreement of the data labels with the positive labels given by the classifier. Hence, it can be thought of as a measure of a classifiers exactness.

Another measure that is typically used in conjunction with precision is the recall measure. Recall is defined as the number of true positives divided by the number of true positives and the number of false negatives. Hence, $Recall = \frac{TP}{TP+FN}$. Recall is used to express the effectiveness of a classifier to identify positive labels.

In order to evaluate the performance of a classifier with a measure that considers both precision and recall, it is possible to make use of the F_{score} . Generally speaking, F_{score} represents the relations between data's positive labels and those given by a classifier. F_{score} is defined as follows: $F_{score} = \frac{(\beta^2+1)TP}{(\beta^2+1)TP+\beta^2FN+FP}$ where β is a positive real constant. The F_{score} that is commonly used is the so-called $F1_{score}$ where the value of β is equal to 1. The $F1_{score}$ score can be interpreted as a weighted average of the precision and recall and it assumes a maximum value of 1 if and only if both precision and recall are equal to 1.

To introduce the AUC (area under the curve) measure, it is necessary to introduce the concept of ROC (Reception Operating Characteristic) curve. As reported in Fawcett (2006), ROC graphs are two-dimensional graphs in which TP rate ($\frac{TP}{TP+FN}$) is plotted on the Y axis and FP rate ($\frac{FP}{FP+TN}$) is plotted on the X axis. A ROC graph depicts relative tradeoffs between benefits (true positives) and costs (false positives). An example of a ROC graph is reported in Fig. 1 where each letter corresponds to a different classifier.

In the ROC space the point (0,0) represents the strategy of never issuing a positive classification; such a classifier commits no false positive errors but also gains no true positives. The opposite strategy, of unconditionally issuing positive classifications, is represented by the upper right point (1,1) (Fawcett, 2006). The point (0,1) represents perfect classification. In order to combine FP rate and the TP rate into a single metric the following steps are performed: firstly the two former metrics are computed considering different threshold (e.g., from 0 to 1 with a step of 0.01), then the corresponding points are plotted on a single graph in the ROC space forming the ROC curve. The resulting metric is the AUC of this curve, which is also referred as AUROC. The value of the AUC ranges between 0 and 1 and the classifier's performance is as better as the AUC is different from 0.5 (this is the AUC of a random classifier).

The performance measures introduce for binary classification problems can be extended also to multi-class classification tasks. The idea is that for an individual class C_i , the assessment is defined by TP_i , FN_i , TN_i , FP_i , $Accuracy_i$, $Precision_i$, $Recall_i$. As reported in Sokolova and Lapalme (2009), the quality of the overall classification is usually assessed in two ways: a measure is the average of the same measures calculated for the possible class labels $C_1, \dots, C_j$ (macro-averaging). The second option is to consider the sum of counts to obtain cumulative TP, FN, TN, FP and then calculating a performance measure (micro-averaging). Macro-averaging treats all classes equally while micro-averaging favors bigger classes. As observed in Lachiche and Flach (2003) as there is no well-developed multi-class ROC analysis, AUC is typically not used to evaluate multi-classification performance.

For a complete review of existing measures for evaluating classifiers' performance, the reader is referred to Sokolova and Lapalme (2009), where authors analyze 24 performance measures used in the complete spectrum of ML classification tasks: binary, multi-class, multi-labeled, and hierarchical. In particular, the paper explains how different evaluation measures assess different characteristics of machine learning algorithms and choosing the correct measure is not a simple task.

Fig. 1 Example of ROC curve.

Current Research and Open Issues

Despite the large number of techniques available to address a classification problem, researchers still continue to investigate the usage of more advanced methods to tackle this task. This section reports current research directions and open issues in this ML area.

A hot research topic is related to the use of evolutionary computation (Bäck *et al.*, 1997) to address classification problems. In fact, while evolutionary computation has been used to successfully solve a plethora of real world problems, its performance to perform multi-class classification is generally poorer with respect to the one produced by other classifiers. Under this light, the work of Ingalalli *et al.* (2014) represents a first attempt to improve the performance of genetic programming (GP) (Koza, 1992) in addressing multi-class classification tasks. GP is one of the youngest techniques inside the family of evolutionary computation and, while it has shown its ability in producing human-competitive results Koza (2010) human, its performance on multi-class problems was not competitive.

The basic idea of the M2GP (Multidimensional Multiclass Genetic Programming) system proposed by Ingalalli *et al.* (2014) is to find a transformation, such that the transformed data of each class can be grouped into unique clusters. In M2GP the number of dimensions in which the clustering is performed is completely independent of the number of classes, such that high dimensional datasets may be easily classified by a low dimensional clustering, while low dimensional datasets may be better classified by a high dimensional clustering (Silva *et al.*, 2016). To achieve this, M2GP uses a representation that is basically the same used for regular tree-based GP, except that the root node of the tree exists only to define the number of dimensions d of the new space. As reported in Silva *et al.* (2016), each candidate classifier is evaluated as follows: (1) all the n instances of the training set are mapped into the new d -dimensional space (each branch of the tree is one of the d dimensions); (2) on this new space, for each of the M classes in the data, the covariance matrix and the cluster centroid is calculated from the instances belonging to that class; (3) the Mahalanobis distance between each sample and each of the M centroids is calculated. Each sample is assigned the class whose centroid is closer.

This system, that has been subsequently extended to an improved method presented in Muñoz *et al.* (2015), has produced, on a large set of benchmarks, performance that are better than or comparable to the ones achieved by random forests, the technique that is able to generally produce the best accuracy with respect to other ML techniques (Fernández-Delgado *et al.*, 2014).

While this example underlines that ML for classification problems is still an open research topic, new challenges should be addressed in connection with the field of Big Data. A list of the most important issues and challenges is reported in Krawczyk (2016) and Kreml *et al.* (2014).

Conclusions

Supervised methods for classification represent an important sub-area of machine learning and they are a valuable tool for addressing problems over different domains. In the field of Bioinformatics, a large number of problems can be formulated as a classification task and successfully solved by means of the existing supervised methods. This article has presented some of the most relevant applications in this field where classification problems arise, describing the most well-known techniques to solve them. Moreover, different measures to evaluate the performance of a classifier have been introduced, showing that, generally, one single measure is not enough to get a meaningful inside about the performance produced by a classification model. The final part of the article was dedicated to recent advances in the field, providing some pointers to the most promising works in the area of machine learning methods for classification problems and discussing challenges and open issues in this field. In particular, one of the most challenging areas is the one related to the development of supervised methods to handle and classify Big Data.

While the provided information represents a gentle introduction to supervised methods for classification, the reader can find a more comprehensive and detailed discussion of the topics covered in this article in Further Reading section.

Unsupervised Learning: Clustering

Clustering

Cluster analysis is an exploratory technique whose aim is to identify groups, or clusters, of high density in which observations are more similar to each other than observations assigned to different clusters.

This process requires to quantify the degree of similarity, or dissimilarity, between observations. The results of the analysis is strongly dependent on the kind of the used similarity metric.

A large class of dissimilarities coincides with the class of distance functions. The most used distance function is the Euclidean distance, defined as the sum of the squared differences of the features between two patterns x_i and x_j :

$$d(x_i, x_j) = \sum_{h=1}^p (x_{ih} - x_{jh})^2$$

where x_{ih} is the h -th feature of x_i .

Similarly, clustering algorithms can use also similarity measures between observations. The correlation coefficient is widely used as a similarity measure

$$\rho(x_i, x_j) = \frac{\sum_h (x_{ih} - \bar{x}_i)(x_{jh} - \bar{x}_j)}{\sqrt{\sum_h (x_{ih} - \bar{x}_i)^2 \sum_h (x_{jh} - \bar{x}_j)^2}}$$

where $\bar{x}_i = \frac{1}{p} \sum_{h=1}^p x_{ih}$ is the average value of the features of a single observation.

Clustering has been widely applied in bioinformatics to solve a wide range of problems. Two of the main problems addressed by clustering are: (1) identify groups of genes that share the same pattern across different samples (Jiang *et al.*, 2004); (2) identify groups of samples with similar expression profiles (Sotiriou and Piccart, 2007).

Many are the different clustering approaches proposed in literature. These methodologies can be divided into two categories represented by the hierarchical and partitive clustering as described in Theodoridis and Koutroumbas (2008).

Hierarchical Clustering

Hierarchical clustering seeks to build a hierarchy of clusters based on a proximity measure.

Hierarchical clustering methods need the definition of a pairwise dissimilarity function and a set of observations as inputs. Hierarchical clustering methods do not define just a partition of the observations, but they produce a hierarchical representation, in which the clustering at a determined level is defined in terms of the clusters of the level below. The lowest level of the hierarchy is made of n clusters, each containing a single observation, whereas at the top level, a single cluster contains all the observations. The absence of a single partition allows the investigator to find the most natural clustering, in the sense of comparing the within cluster similarity to the between cluster similarity.

Strategies for accomplishing hierarchical clustering can be divisive or agglomerative. The former is a “top down” approach where all the observations are in one cluster and then are splitted recursively moving down into the hierarchy. The latter is a “bottom up” approach where, initially, each pattern is a “singleton” cluster and then pairs of clusters are merged moving up into the hierarchy.

Agglomerative clustering is the most used approach to construct clustering hierarchies. It starts with n clusters, each one containing only one observation. At each step the two most similar clusters are merged and a new level of the hierarchy is added. The procedure ends in $n - 1$ steps, when, at the top of the hierarchy, the last two clusters are merged.

The most used methods to perform hierarchical cluster analysis are the single linkage, the complete linkage and the average linkage.

Single Linkage

In this method, the distance between two clusters is represented by the distance of the pair of the closest data patterns belonging to different clusters. More formally, given two clusters G and H and a distance function d , the single linkage dissimilarity is defined as:

$$d_S = \min_{x_i \in G, x_j \in H} d(x_i, x_j)$$

Single linkage method is able to identify clusters of different shapes and to highlight anomalies in the data distribution better than the other hierarchical techniques. On the other side, it is sensitive to noise and outliers. Moreover it can results in clusters that represents a chain between the patterns. This can happens when clusters are well-outlined but not well separated. An illustration of how the algorithm works is in the top-left part of Fig. 1.

Fig. 1 The distance between any couple of clusters can be defined in different ways, resulting in different hierarchies. The left side of the figure shows two different clusters in two different colours, with the centroids of the clusters represented by circles. The green lines represent the different alternative distances between clusters. The corresponding dendrograms are shown next to each different distance definition.

Complete Linkage

In this method the distance between two clusters is represented by the distance of the pair of the farthest data points belonging to different clusters. More formally, given two clusters G and H and a distance function d , the complete linkage dissimilarity is defined as:

$$d_C = \max_{x_i \in G, x_j \in H} d(x_i, x_j)$$

This method identifies, above all, clusters of elliptical shape. This algorithm prefers the homogeneity between the elements of the group at the expense of differentiation between the groups. An illustration of how the algorithm works is in the center-left part of Fig. 1.

Average Linkage

The distance between two clusters is represented by the average distance of all pairs of data points belonging to different clusters. More formally given two clusters G and H and a distance function d , the average linkage dissimilarity is defined as:

$$d_A = \frac{1}{|G||H|} \sum_{i \in G} \sum_{j \in H} d(x_i, x_j)$$

where $|G|$ and $|H|$ are respectively the number of observations in clusters G and H . The average linkage produces clusters relatively compact and relatively separated. As a drawback, if the measurements of the two clusters to join are very different the distance will be very close to that of the largest cluster. Moreover, the average linkage is susceptible to strictly increasing transformations of the

dissimilarity, changing the results. On the contrary, single and complete linkages are invariant to such transformations as described in [Friedman et al. \(2001\)](#). An illustration of how the algorithm works is in the bottom-left part of [Fig. 1](#).

Dendrogram Representation

Regardless of the aggregation criterion, the produced hierarchy of clusters can be graphically represented by a binary tree called dendrogram. Each node on the dendrogram is a cluster while each leaf node is a singleton cluster (i.e., an input pattern or observation). The height of the tree measures the distance between the data points. An example is reported in [Fig. 1](#), where each tree corresponds to one of the aggregation criteria above defined. The clustering algorithms are performed on a toy dataset of ten data points. The height of each node is proportional to the dissimilarity between the corresponding merged clusters. Figures were accomplished by using the *ggplot2* package included in R. An in-depth description of the library can be found in [Wickham \(2009\)](#).

The dendrogram can be a useful tool to explore the clustering structure of the data at hand. Data clustering can be obtained by cutting the dendrogram at the desired height, then each connected component forms a cluster. Inspection of the dendrogram can help to suggest an adequate number of clusters presents in the data. This number and the corresponding data clustering can be used as the initial solution of more elaborate algorithms.

k-Means

The *k*-means, proposed by [MacQueen et al. \(1967\)](#), is one of the most used and versatile clustering algorithm. The goal of *k*-means is to partition the observations into a number *k* of clusters. Each cluster contains the patterns that are more similar to each other while those dissimilar to the observations are put into other clusters. A pattern, called centroid, that is computed as the centre of mass of all the observations belonging to the cluster, is the representative prototype of all these points.

Formally, let $X = \{x_1, \dots, x_n\}$ be a set of *N* points in a and let *K* be an integer value, the *k*-means algorithm seeks to find a set of *k* vectors μ_k that minimise the Within Cluster Sum of Squares (WCSS)

$$WCSS = \sum_{h=1}^k \sum_{x_i \in C_h} d(x_i, \mu_h)$$

where C_h is the *h*-th cluster and μ_h is the corresponding centroid.

The *k*-means algorithm is a two-step iterative procedure that starts by defining *k* random centroids in the feature space, each corresponding to a different cluster. Then, the patterns are assigned to the nearest centroid by using the Euclidean distance. Afterwards, each centroid is recomputed as the mean (center of mass) of the observations belonging to the same cluster. Each step is proven to minimise the WCSS until convergence to a local minimum. The assignment and recomputing steps alternate until no observation is reassigned.

The *k*-means algorithm, as described in [Jung et al. \(2014\)](#), is the following:

Algorithm 1: *k*-Means Clustering Algorithm

1. ***k*-means** (*k*, *X*);
 Input: The number *k* and a database *X* containing *n* patterns
 Output: A set of *k*-clusters that minimizes the squared-error criterion
 2. Randomly choose *k* patterns as the initial cluster centroids;
 3. repeat;
 4. (re)assign each pattern to the cluster corresponding to its nearest centroid;
 5. update the cluster centroid, i.e., for each cluster, calculate the mean value of its patterns;
 6. until no change.
-

It must be noted that this algorithm strongly depends on the initial assignment of the centroids as shown in [Fig. 2](#). Usually, if a prior knowledge about the location of the centroids does not exist, this algorithm can be run many times with different initial solutions, randomly sampled from the data observations and keeping the best solution. The number *k* of clusters is a hyper-parameter to be estimated, and different choices of it are usually compared. Note that the WCSS is a decreasing function with respect to *k*, so that care must be taken in performance comparisons with increasing values of *k*. Different heuristics to find an appropriate *k* have been proposed, ranging from graphical models to evaluate how well a point fits within its cluster, like the silhouette, described by [Rousseeuw \(1987\)](#), to information theoretic criteria that penalise the WCSS to find the right trade-off between maximum information compression (one cluster) and minimum loss of information (*n* clusters, one for each observation).

Expectation Maximisation (EM)

Another important category of clustering algorithms is the one that includes model based approaches. Here the main idea is that each cluster can be represented by a parametric distribution, such as a Gaussian or a Poisson for continuous or discrete data, respectively.

Fig. 2 *k*-Means results with different *k* values in input. A black X represents the cluster centroid.

More formally, let $X = \{x_1, \dots, x_n\}$ be n observed data vectors and let $Z = \{z_1, \dots, z_n\}$ be the n values taken by the hidden variables (i.e., the cluster labels). The expectation maximisation algorithm attempts to find the parameters θ that maximise the log probability $L(\theta) = \log P(X|\theta) = \log \sum_Z p(X, Z|\theta)$ of the observed data, where both θ and Z are unknown.

To deal with this problem, the task of optimising $\log p(X|\theta)$ is divided into a sequence of simpler sub-problems, that guarantees that their corresponding solutions $\hat{\theta}^{(1)}, \hat{\theta}^{(2)}, \dots$ converge to a local optimum of $\log P(X|\theta)$.

More specifically, the EM algorithm alternates between two phases. In the E-step, it chooses a function f_t that lower bounds $\log P(X|\theta)$ and for which $f_t(\hat{\theta}^{(t)}) = \log P(X|\hat{\theta}^{(t)})$. In the M-step, the EM algorithm find a new parameter set $\hat{\theta}^{(t+1)}$ that maximizes f_t . Since the value of f_t matches the objective function at $\hat{\theta}^{(t)}$, it follows that $\log P(X|\hat{\theta}^{(t)}) = f_t(\hat{\theta}^{(t)}) \leq f_t(\hat{\theta}^{(t+1)}) = \log P(X|\hat{\theta}^{(t+1)})$. This proves that the objective function monotonically increases at each iteration of EM leading to the algorithm convergence.

Similar to the *k*-means algorithm, EM is an iterative procedure: the E-step and M-step are repeated until the estimated parameters (means and covariances of the distributions) or the log-likelihood do not change anymore.

Mainly, we can summarize the EM clustering algorithm as described in [Jung et al. \(2014\)](#) as follows:

The EM technique is quite similar to the *k*-means. The EM algorithm extends this basic approach to clustering into two important ways:

- The EM clustering algorithm computes probabilities of cluster memberships based on one or more probability distributions. Therefore, the goal of the algorithm is to maximise the overall probability or likelihood of data, given the (final) clusters. See [Fig. 3](#).
- Unlike the classical implementation of *k*-means, the general EM algorithm can be applied to both continuous and categorical variables.

Fig. 3 EM clustering results. The (a) panel shows how the points are assigned to each cluster. The (b) panel shows the uncertainty in the assignment: as we can see, there is a higher confidence in the assignment of the points to the red cluster, while there is some uncertainty between the green and blue clusters. Smaller points have less uncertainty in the assignment.

Algorithm 2: EM clustering algorithm

1. $\underline{\text{EM}}(k, X, \text{eps})$;
Input: Cluster number k , a database X , stopping tolerance eps
Output: A set of k -clusters with weights that maximise the log-likelihood function
 2. Expectation step: For each database record x , compute the membership probability of x in each cluster $h = 1, \dots, k$.
 3. Maximization step: Update mixture model parameters (probability weights).
 4. Stopping criteria: If stopping criteria are satisfied (convergence of parameters and log-likelihood) then stop, else set $j = j + 1$ and go to (2).
-

Different from k -means, the EM algorithm does not compute actual assignments of observations to clusters, but classification probabilities. In other words, each observation belongs to each cluster with a certain probability. Of course, as a final result an actual assignment of observations to clusters can be computed based on the (highest) classification probability.

External Clustering Quality Measures

In order to compare the clustering results with prior knowledge related to real class membership values, several indexes can be used. Some examples are the Rand Index, the Purity Index and the Normalised Mutual Information.

Rand Index

Let $S = o_1, \dots, o_n$ be a set of n elements and X and Y be two of its partitions to compare, where $X = X_1, \dots, X_r$ is a partition of S into r subsets and $Y = Y_1, \dots, Y_s$ is a partition of S into s subsets, we can define the following measures: (i) a , is the number of element pairs in S that are in the same subset both in X and in Y ; (ii) b is the number of element pairs in S that are in different subsets both in X and in Y ; (iii) c is the number of element pairs in S that are in the same subset in X and in different subsets in Y ; (iv) d is the number of element pairs in S that are in different subsets in X and in the same subset in Y . The Rand Index R is defined as:

$$R = \frac{a + b}{a + b + c + d} = \frac{a + b}{\binom{n}{2}}$$

Intuitively, $a + b$ can be considered as the number of agreements between X and Y and $c + d$ as the number of disagreements between X and Y . Since the denominator is the total number of pairs, the Rand Index represents the occurrence frequency of agreements over the total pairs.

Purity

Purity is one of the most useful external criteria for clustering quality evaluation, when prior knowledge on real class memberships is available. To compute purity, each cluster is labelled with the class which represents the majority of the points it contains.

Then the accuracy of this assignment is measured by counting the number of correctly assignments divided by the number of points.

Given a set of N elements, their clustering partition $\omega = \{\omega_1, \omega_2, \dots, \omega_K\}$ and their real set of classes $C = \{C_1, C_2, \dots, C_J\}$ the purity measure is defined as following:

$$\text{purity}(\omega, C) = \frac{1}{N} \sum_k \max_j |w_k \cap c_j|$$

where w_k is the set of elements in the cluster ω_k and c_j is the set of elements of class C_j .

Normalised Mutual Information

The Mutual Information (MI) of two random variables is a measure of their mutual dependence. It quantifies the amount of information that a variable can give about the other. Formally, the MI between two discrete random variables X and Y is defined as:

$$I(X, Y) = \sum_{y \in Y} \sum_{x \in X} p(x, y) \log \left(\frac{p(x, y)}{p(x)p(y)} \right)$$

where $p(x, y)$ is the joint probability distribution function of X and Y and $p(x)$ and $p(y)$ are the marginal probability distribution functions of X and Y , respectively.

The concept of MI is intricately linked to that of Entropy of a random variable, a fundamental notion in Information Theory, that defines the “amount of information” held in a random variable.

The MI measure is not upper limited, then the Normalised Mutual Information (NMI) measure has been defined as:

$$R = \frac{I(X, Y)}{H(X) + H(Y)}$$

where $H(X)$ and $H(Y)$ are the entropies of X and Y , respectively. NMI ranges between 0 and 1, with 0 meaning no agreement between the two variables and 1 meaning complete agreement.

An Example of Cluster Analysis Application to Patient Sub-Typing

As noticed by [Saria and Goldenberg \(2015\)](#), many diseases, such as cancer or neurodegenerative disorders, are difficult to diagnose and to treat because of the high variability among affected individuals.

Precision medicine tries to solve this problem by identifying individual variability in gene expression, lifestyle and environmental factors ([Hood and Friend, 2011](#)). The final aim is to better predict disease progression and transitions between the disease stages and targeting the most appropriate medical treatments ([Mirmezami et al., 2012](#)).

A central role in precision medicine is played by patient sub-typing, whose aim is to identify sub-populations of patients that share similar behavioural patterns. This can lead to more accurate diagnostic and treatment strategies. From a clinical point of view, refining the prognosis for similar individuals can reduce the uncertainty in the expected outcome of a treatment on individuals.

In the last decade, the advent of high-throughput technologies has provided the means for measuring differences between individuals at the cellular and molecular levels. One of the main goals driving the analyses of high-throughput molecular data is

Fig. 4 3D-MDS dataset representation of the example described in the text.

the unbiased biomedical discovery of disease sub-types via unsupervised techniques, such as cluster analysis (Sorlie *et al.*, 2001; Serra *et al.*, 2015; Wang *et al.*, 2014).

Here we report an example of application of the hierarchical, *k*-means and EM algorithms to the clustering of patients affected by breast cancer.

The dataset is related to 20 breast cancer patients randomly selected from the TCGA repository (Breast invasive carcinoma (BRCA) – see Relevant Website section). The patients are divided into four classes (Her2, Basal, LumA, LumB), using the PAM50 classifier described in Tibshirani *et al.* (2002). Data are pre-processed as in Serra *et al.* (2015). Since gene expression data are high dimensional (more than 20 k genes), genes were grouped into 100 clusters and only the cluster prototypes were used as features for the patient clustering task. Moreover, for clarity purpose, only 5 random patients for each class are used in this example. In Fig. 4 the 3D multidimensional scaling projection of the dataset is reported.

All the experiments were performed by using the Euclidean distance and by setting the number of clusters to the same number of classes ($k=4$). Fig. 5 shows the results of the applied clustering algorithms. For each method, the true patient classes are represented by different shapes and the cluster assignments by different colours. As we can see from Fig. 5 and from Table 1 the clustering assignment that best resembles the real classes is the *k*-means, being that with the highest rand index (0.87), purity (0.85) and NMI (0.72), meaning that each cluster contains a majority of patients of the same class.

Figures were accomplished by using the *ggplot2* package included in R.

Fig. 5 *k*-Means, EM and Hierarchical clustering results with 4 clusters. In the scatters the shapes represent the true patient classes, while the colours represent the cluster assignments of each algorithm.

Table 1 External validation index for clustering evaluations

	<i>Complete</i>	<i>Single</i>	<i>Average</i>	<i>k-Means</i>	<i>EM</i>
Rand index	0.81	0.38	0.63	0.87	0.81
Purity	0.75	0.40	0.55	0.85	0.75
NMI	0.65	0.23	0.39	0.72	0.65

Note: The results of the different clustering algorithms were compared with the true patient classes.

Introduction

Modern technologies allow collecting enormous amount of data in every field of human activity and regarding every aspect of human life. Industry, science, medicine, individuals in their day-to-day life produce data that can and must be analyzed because it often hides valuable knowledge, but this analysis can not be done by humans alone, even tough domain experts, since data generation happens at rates and in such volumes that traditional techniques are useless.

Data Mining is the discipline which deals with the process of extracting useful knowledge from large volumes of data (Han *et al.*, 2011). Its goal is to find knowledge that can ease comprehension and insight and can support decision-making with regard to the phenomena that have generated the data. In the context of data mining, data is the raw material which has to be excavated for knowledge, hence, differently from the meaning of similar expressions, for example, *gold mining*, data mining stands for mining *into* data and not *in search of* data.

Data Mining is an interesting and very active area of research, which has been received even more attention in the last decades. Although it is often confused with the general process of knowledge discovery from data, the term data mining refers to the core step of a wider pipeline of activities concerning the treatment of data for knowledge discovery. This pipeline includes the creation of the data set to analyze, by selecting and integrating data from possibly multiple sources; the cleaning and preprocessing of the data set, by deleting noisy and inconsistent data; the data transformation, which consists of reducing and transforming the data set to shape it in a form suitable for the analysis; the data mining step, which includes the choice of the mining task to accomplish (summarization, classification, clustering, pattern mining, etc.) and the selection and execution of the mining algorithm; at last the interpretation, evaluation and presentation of the results obtained (Aggarwal, 2015; Rajaraman *et al.*, 2012; Zaki and Wagner Meira, 2014).

The mining of frequent patterns, association rules, and correlations is one of the possible data mining tasks that one would want to accomplish, beyond being one of the most studied (Aggarwal and Han, 2014). In general, a pattern is some kind of scheme or configuration which recurs in the data. Based on the type of data analyzed, a pattern can consist of a set of items, or a subsequence, or a substructure, such as a subgraph or subtree. Frequent patterns are patterns that occur frequently in a data set, for example, set of items that appear together in more than a given fraction of the whole data set. Frequent patterns are important in order to determine associations and correlations among data and also as a possible useful component of other mining tasks, such as classification and clustering.

Association rules mining has been introduced in the context of market-basket analysis (Agrawal *et al.*, 1993), i.e., the analysis of products that customers purchase in a single visit to the store in search of sets of products frequently bought together. But since the first formulation, frequent pattern mining has become a data mining tool extensively used in a wide variety of domains and also employed as an intermediate step for other data mining tasks, such as classification and clustering. It has been applied to document sets analysis (Beil *et al.*, 2002; Boley *et al.*, 1999; Fung *et al.*, 2003), web log mining, for example, searching for the set of pages more likely to be accessed together during the same session by a user (Ivancsy and Vajk, 2006; Mobasher *et al.*, 1996), recommender systems (Lin *et al.*, 2002; Mobasher *et al.*, 2001), and anomaly detection (Lee *et al.*, 1998; Leung and Leckie, 2005).

Furthermore, recently, frequent pattern mining has been successfully adopted in life sciences data analysis. It has been applied to medical and biological data (Atluri *et al.*, 2009; Naulaerts *et al.*, 2015), for better disease diagnosis, or to improve the knowledge about what causes particular diseases, and for a wide range of specific bioinformatics problems, including annotation mining, structural motif discovery and biclustering of expression profiles.

In this article, we introduce in Section Basic Concepts the basic notions of frequent itemsets, associations and correlations in the context of transaction records. In the same Section, we also discuss some measures of interestingness and usefulness of associations among itemsets and in Section Frequent Itemset Mining algorithms we describe some algorithms that allow efficiently mining frequent itemsets.

Basic Concepts

In this section, we introduce and formalize the basic concepts which underlie the mining of frequent itemsets in transactional data sets and the derivation of interesting associations and correlations among the analyzed data. As a concrete example, we shall refer to the market-basket analysis, which consists in analyzing the business transaction records of a supermarket in order to find interesting associations among the items (products) that appear together in the shopping carts of customers.

A way to express co-occurrence relationships among items that appear in transactional data sets is by means of association rules. An association rule is an implication of the form $A \Rightarrow B$, where both A and B are set of items and $A \cap B = \emptyset$. It suggests that it is likely for a transaction which contains the itemset A , called the *antecedent* of the rule, to also contain the itemset B , called the *consequent* of the rule. In the context of market-basket analysis, for example, $\{bread\} \Rightarrow \{butter\}$ indicates that it is likely for a

customer who buys bread to also buy butter in the same trip to the supermarket. Finding association rules that describe the customer behaviours can greatly help in delineating successful marketing strategies, for example, a retailer can organize her shelves so that butter is positioned close to bread in order to ease the purchase of both the products. Otherwise, a completely different strategy could consist in placing the butter far from the bread so that a customer who buys bread needs to pass other shelves and is tempted by different products in its way toward the butter. The kind of knowledge brought to the retailer by association rules can also be helpful in planning a good price policy, for example, a discount on the bread can be paired with an increase in the price of butter: it is unlikely that a customer attracted by the discount on bread chooses to give up on butter owing to the higher price.

Frequent Itemsets and Association Rules

Let $\mathcal{U}$ be the universe of items, i.e., the set of all of the possible items that can appear in a data set. We also refer to a generic set of items drawn by $\mathcal{U}$ as an *itemset* and to a set of precisely k items as a *k-itemset*. A transaction is a set of items drawn by $\mathcal{U}$ and a transaction database consists of a set of transactions. Let $\mathcal{D} = \{T_1, T_2, \dots, T_n\}$ be a database of n transactions to be mined. Each transaction T_i in $\mathcal{D}$ is represented by a unique identifier TID_i , $i = 1, 2, \dots, n$, called *transaction ID*.

Definition 1: (the support of an itemset). Given an itemset I , the support of I with reference to a transaction database $\mathcal{D}$ is the fraction of transactions in $\mathcal{D}$ that contain I as a subset. The support of the itemset I , denoted by $sup(I)$, is defined as $sup(I) = \frac{|\{T_i \in \mathcal{D} \mid I \subseteq T_i\}|}{|\mathcal{D}|}$, where $|\mathcal{D}|$ is the total number of transactions in $\mathcal{D}$.

Alternatively, we can consider only the number of transactions that contains a given itemset. We refer to this number as the *support count* of the itemset, $sup_count(I) = |\{T_i \in \mathcal{D} \mid I \subseteq T_i\}|$.

The support of an itemset A represents an estimate of the probability $P(A)$ of finding that itemset in the data set. An itemset is *frequent* if it appears in a fraction of transactions which exceeds a minimum support threshold fixed by the data miner and specific to the mining task.

Definition 2: (frequent itemsets). Given a transaction database $\mathcal{D}$, an itemset I with support $sup(I)$ in $\mathcal{D}$, and a predefined minimum support threshold, $minsup$, the itemset I is said to be frequent if $sup(I) \geq minsup$.

A transaction data set can be easily represented as a table of transactions with each row consisting of a transaction ID and the set of items in the transaction. A transaction itemset, in turn, can be represented by a set of items or by a binary vector of length $|\mathcal{U}|$ where each bit represents an item in $\mathcal{U}$ and is set or unset on the basis of the presence of that item in the transaction. This representation of a data set is referred to as *horizontal*. Table 1 shows an example of database in horizontal form, borrowed as usual from the market-basket analysis domain. The table refers to the universe set of items $\mathcal{U} = \{\text{bread, butter, cheese, milk, water}\}$.

Alternatively, a database of transactions can be represented in *vertical* form, as a table that reports for each item the set of transactions (transaction IDs) that contain that item (this set is also referred to as *tidset*). We refer to the tidset of an itemset X as $T(X)$. Also for the vertical representation, the tidset can be written as a binary vector, where each transaction is mapped to a bit whose value is one if the item belongs to the transaction and zero otherwise. Table 2 shows the same database of Table 1 but in vertical form.

In the data set showed in Tables 1 and 2, the itemset $I = \{\text{bread, butter}\}$ has support count $sup_count(I) = 3$ and its support expressed as a percentage is $sup(I) = 50\%$, therefore the itemset occurs in 50% of all of the transactions of the database, i.e., three

Table 1 Example of a horizontal database

Transaction ID	Itemset	Binary representation
1	{milk, bread}	10010
2	{bread, butter}	11000
3	{bread, cheese}	10100
4	{milk, bread, butter}	11010
5	{bread, butter}	11000
6	{milk, water}	00011

Table 2 Example of a vertical database

Item	Tidset	Binary representation
Milk	{1, 4, 6}	100101
Bread	{1, 2, 3, 4, 5}	111110
Butter	{2, 4, 5}	010110
Cheese	{3}	001000
Water	{6}	000001

out of six transactions. If we set a minimum support threshold equal to 30%, then the itemsets {bread, butter} and {bread, milk} are frequent 2-itemsets, whilst the itemset {bread} is a frequent 1-itemset or frequent item.

Finding frequent itemsets is the first step toward the discovery of association rules. It is the most computationally intensive and, therefore, it has been the main focus of data mining researchers. Once the frequent itemsets of a data set are computed, the second step simply consists in considering each frequent itemset I and enumerating the possible association rules of the form $X \Rightarrow I \setminus X$, with $X \subset I$, discarding all of the rules judged as not useful or not interesting.

Two measures of interestingness usually adopted in the generation of association rules are *support* and *confidence*. Rules with support and confidence above specified thresholds are said to be strong and selected for output. Let us formally define these two metrics.

Definition 3: (support of an association rule). *Given an association rule $A \Rightarrow B$, the support of the rule is defined as*

$$\text{sup}(A \Rightarrow B) = \frac{\text{sup}(A \cup B)}{|D|}.$$

Definition 4: (confidence of an association rule) *Given an association rule $A \Rightarrow B$, the confidence of the rule is defined as*

$$\text{conf}(A \Rightarrow B) = \frac{\text{sup}(A \cup B)}{\text{sup}(A)}.$$

The support of an association rule coincides with the support of the itemset from which the rule is generated. It is an indication of how often the rule can be applied to a given input dataset. A rule whose support is very low may occur in the input dataset only by chance. Moreover, low support rules are likely to be, in general, not interesting (from a business oriented perspective, it may not be profitable promoting items rarely bought together by customers).

On the other hand, the confidence metrics measures how reliable the inference made by a rule is. For a given association rule $A \Rightarrow B$, a higher confidence value means that it is more likely for B to be present in transactions that contain A . By its definition, the confidence of a rule can also be interpreted as an estimate of the conditional probability of B given A , $P(B|A)$.

Definition 5: (strong association rules) *Let A and B be two sets of items and let minsup and minconf be respectively a predefined minimum support threshold and minimum confidence threshold. Then, the association rule $A \Rightarrow B$ is said to be strong if it satisfies both the following criteria:*

1. *The support of the itemset $A \cup B$ is at least minsup (itemset $A \cup B$ is frequent);*
2. *The confidence of the rule $A \Rightarrow B$ is at least minconf .*

The minimum support threshold and minimum confidence threshold are usually defined by the data miner on the basis of the specific domain and application. The former is used in the determination of the frequent itemsets, in the first step. The latter is employed in the second step, when association rules are generated from the frequent itemsets, in order to select only strong rules.

Closed and Maximal Frequent Itemsets

We note that if an itemset I occurs in a transaction, then all of its subsets will also be contained in the same transaction. This simple observation leads to the following property, referred to as the *support monotonicity property*.

Property 1: (support monotonicity). *The support of any non-empty subset J of an itemset I is always at least equal to the support of I :*

$$\text{sup}(J) \geq \text{sup}(I) \quad \forall J \subseteq I.$$

An immediate consequence of monotonicity of support is that every subset of a frequent itemset is also frequent. This property is referred to as *downward closure*.

Property 2: (downward closure). *Every non-empty subset of a frequent itemset is also frequent.*

The downward closure allows efficiently pruning the search space. In fact, if an itemset I is not frequent, then any superset $K \supseteq I$ cannot be frequent and can be discarded.

Following straight from the definition of confidence and the property of support monotonicity, a monotonicity property is also valid for the confidence of association rules.

Property 3: (confidence monotonicity). *Let X_1 , X_2 and I be itemsets such that $X_1 \subset X_2 \subset I$. Then the confidence of $X_2 \Rightarrow I \setminus X_2$ is at least that of $X_1 \Rightarrow I \setminus X_1$:*

$$\text{conf}(X_2 \Rightarrow I \setminus X_2) \geq \text{conf}(X_1 \Rightarrow I \setminus X_1).$$

Considering the downward closures, it is easy to see that the number of frequent itemsets of a data set can quickly grow and become unmanageable, especially if long frequent itemsets are present. In fact, if a 30-itemsets is frequent also its 2^{30} possible non-empty subsets are frequent. To overcome this problem, two particular classes of frequent itemsets have been introduced, the *closed frequent itemsets* and the *maximal frequent itemsets*.

Definition 6: (closed frequent itemsets). *Given a minimum support minsup , a frequent itemset I is closed if $\text{sup}(I) \geq \text{minsup}$ (i.e., I is frequent), and none of its supersets have exactly the same support $\text{sup}(I)$.*

Definition 7: (maximal frequent itemsets). *Given a minimum support minsup , a frequent itemset I is maximal if $\text{sup}(I) \geq \text{minsup}$ (i.e., I is frequent), and no superset of I is frequent as well.*

Fig. 1 shows the set relationships among frequent itemsets, closed frequent itemsets and maximal frequent itemsets.

It can be shown that from the set of closed frequent itemsets the complete set of frequent itemsets and their supports can be derived, so that closed frequent itemsets are a compressed and more manageable way of representing frequent itemsets. On the other hand, although smaller, the same can not be said for the set of maximal frequent itemsets, from which one can derive the identity of all of the frequent itemsets but not their supports.

Fig. 1 Set relationships among frequent, closed and maximal itemsets.

Fig. 2 Example of a lattice: green nodes are frequent itemsets, red marked green nodes are closed frequent itemsets, double red bordered green nodes are maximal frequent itemsets.

Table 3 Example of transaction database

Transaction ID	Itemset
1	{a, c, d}
2	{a, b, e}
3	{c, d, e}
4	{a, b, c, e}
5	{a, b, c, d, e}
6	{c, e}
7	{a, b, c, e}

There exists a simple graphical representation of itemsets, called a *lattice*, shown in Fig. 2. A lattice is a graph $G=(V, E)$ in which V is the set of vertices, each one representing an itemset, with $|V| = 2^{|\mathcal{U}|}$, and E is the set of edges, where an edge connects a pair of vertices *iff* (if and only if) the corresponding itemsets differ by exactly one item.

The lattice is a natural representation of the search space of frequent itemsets. Since the number of itemsets in the lattice is exponential (being the power set of the universe $\mathcal{U}$), a brute-force frequent pattern mining algorithm trying to explicitly traverse the lattice can not be efficient. Pruning the search space by implicitly traversing the lattice is therefore a common feature of all of the frequent pattern mining algorithms. Fig. 2 refers to the set of transactions in Table 3: for each itemset the IDs of the transactions containing it are indicated. Green nodes in Fig. 2 are frequent itemsets, whilst green nodes with a marked red border are closed frequent itemsets; nodes with a double red border are maximal frequent itemsets.

Correlation and Implication Rules

Although the minimum support and confidence thresholds help to discard many uninteresting association rules and these two measures are actually used by several algorithms, in many contexts they do not suffice to capture the degree of correlation and implication between antecedent and consequent of a rule. For this reason, additional correlation and implication measures can be evaluated along with support and confidence (Brin *et al.*, 1997a,b). When we augment the support-confidence framework with a correlation measure, we also refer to association rules as *correlation rules*.

We consider here a particular correlation measure called *lift* or *interest*. Lift allows quantifying the correlation of the two itemsets involved in an association rule. Let us consider the rule $A \Rightarrow B$, if the occurrence of A in a transaction is independent from the occurrence of B then $P(A \cup B) = P(A)P(B)$, otherwise the two occurrences are correlated. Lift is computed as following

$$\text{lift}(A \Rightarrow B) = \frac{P(A \cup B)}{P(A)P(B)} = \frac{\text{conf}(A \Rightarrow B)}{\text{sup}(B)} \quad (1)$$

Unlike confidence, lift also takes into account $P(B)$ and allows overcoming the main weakness of the confidence metrics, which can be high and lead to valid rules also in case of uncorrelated or negatively correlated itemsets. In fact, lift reveals and measures both positive and negative correlations. If the lift value of an association rule is greater than 1, then antecedent and consequent are positively correlated, i.e., it is likely that the occurrence of one leads to the occurrence of the other. If the lift value is less than 1, then the antecedent is negatively correlated with the consequent, i.e., it is likely that the occurrence of one leads to the absence of the other. If the lift value is equal to 1, then antecedent and consequent are independent and there is no correlation between their occurrences.

Lift measurement allows improving on the support-confidence framework quantifying the degree of correlations between antecedent and consequent occurrences, but the computed correlation is not directional and does not measure the degree of implication. Another metric has been introduced for this purpose, called *conviction*, and the term *implication rule* is used in place of association rule when this measure is adopted. It is computed as:

$$\text{conv}(A \Rightarrow B) = \frac{P(A)P(\overline{B})}{P(A \cup \overline{B})} \quad (2)$$

Differently from lift, conviction is a measure of implication: it is directional and equal to one when antecedent and consequent are unrelated. A value greater than 1 indicates a relationship of implication between antecedent and consequent: the stronger the implication, the greater the value, up to infinity for implications which are always valid.

Frequent Itemset Mining Algorithms

In this section, we describe three classical algorithms for frequent itemsets and association rules mining, which represent three different fundamental approaches to this problem: the seminal algorithm by Agrawal and Srikant (1994) called Apriori; Eclat, an algorithm by Zaki (2000) exploiting the vertical database format; and FP-growth, by Han *et al.* (2000), which solves the problem of association rule mining without recurring to candidate generation. We shall focus on the first and more costly

step of association rule mining, i.e., how the three algorithms solve the problem of finding the frequent itemsets of a transaction database. The presentation is based on Han *et al.* (2011), Zaki and Wagner Meira (2014).

Apriori

The main characteristic of Apriori algorithm is its level-wise (breadth-first) exploration of the itemset lattice (see Fig. 2) in search of the frequent itemsets. Starting with the frequent 1-itemsets, for $k \geq 2$, it proceeds first by discovering all of the frequent itemsets of length k , and then computing the frequent $(k + 1)$ -itemsets. In fact, at each level, the computation leverages the knowledge acquired at the previous level.

The algorithm starts by identifying the set L_1 of the frequent 1-itemsets, i.e., the frequent items of the database to be mined. This step requires a first scan of the database. Then, at each subsequent value of $k \geq 2$, where k is the length of the itemsets computed in the current iteration, the set L_{k-1} of the frequent $(k - 1)$ -itemsets is used to generate the set of k -itemsets that are candidate to be frequent. The generated set, C_k , is a superset of the set of frequent k -itemsets, therefore, a scan of the database is required in order to compute the actual support of each candidate and filter out the candidates whose support is below the *minsup* threshold. The remaining itemsets, after the pruning, are all frequent and form the set L_k . The two phases of candidate generations and frequent itemsets determination alternates until no more frequent itemsets are found.

The candidate generation phase of each iteration is optimized by taking advantage of the downward closure property of frequent itemsets, i.e., the fact that all of the subsets of a frequent itemset must be frequent as well. The property is used to reduce the number of candidates in C_k by eliminating all of the candidates that can not be frequent since they have a $(k - 1)$ -subset which is not frequent, i.e., it is not present in L_{k-1} .

The pseudo-code for Apriori is shown in Algorithm 1. The procedure `APRIORI_GEN` deals with the generation of the candidate set C_k starting from the frequent $(k - 1)$ -itemsets already computed in the previous iteration. The candidate generation requires two steps. The first step consists in a join involving the set $\mathcal{L}_{k-1}$ with itself. Taking into account that there exists a lexicographic order among itemsets and items in itemsets are ordered, a new k -itemset is generated from two itemsets l_1 and l_2 in $\mathcal{L}_{k-1}$, where $l_1 < l_2$, and the first $(k - 2)$ items are the same in both l_1 and l_2 , by appending to l_1 the last item in l_2 . The second step checks whether all of the $(k - 1)$ -subsets of each generated k -candidate are frequent, i.e., they are in $\mathcal{L}_{k-1}$. If the candidate passes the test, it is added to C_k , otherwise it is discarded.

Eclat

The Equivalence CLASS Transformation (Eclat) algorithm is based on a vertical representation of the transaction database and adopts a divide and conquer approach along with a depth-first search strategy to explore the itemset lattice in search of frequent itemsets.

Thanks to the vertical database format, the cost of support counting is reduced and it becomes possible to determine it during the candidate generation. In fact, the support of a k -itemset can be computed by intersecting the tidsets corresponding to all of its items, or alternatively, to two of its $(k - 1)$ -subsets whose join can produce it. On the other hand, the divide and conquer approach and the depth-first search strategy allow reducing the database scans by dividing the itemset lattice, i.e., the search space, in sub-lattices formed by itemsets that share a common prefix (equivalence classes), and, correspondingly, by dividing the transaction database into conditional databases, each one containing the transactions in the original dataset that refer to the itemsets in the corresponding sub-lattice.

The pseudocode for `ECLAT` is shown in Algorithm 2. The algorithm recursively explores the sub-lattices (equivalence classes) formed by the itemsets with a common prefix and compute their support in order to detect the frequent itemsets. Initially, the frequent items are considered already computed and used to define the starting equivalence classes. Once the equivalence class corresponding to a given prefix is completely explored (in a recursively depth-first search fashion), the algorithm proceeds by considering another class (i.e., the class of itemsets having a different prefix).

One of the weaknesses of Eclat is that the tidsets can be too long to be stored in the main memory and to efficiently compute their intersection. It is worth noting here that, regarding this problem, a variant called `dEclat` of the original algorithm has been proposed in which the performances of Eclat are improved through a careful shrinking of the size of the intermediate tidsets. This algorithm keeps track of the differences in the tidsets as opposed to the full tidsets.

FP-Growth

The FP-growth algorithm exploits a divide and conquer approach similar to Eclat, but with reference to an horizontal database format. It uses a special data structure, an augmented prefix tree called frequent pattern tree (FP-tree) which contains, in a compressed form, all of the information of the input transaction database needed to compute the itemset supports.

The vertices of the tree are labeled with a single item, and each child vertex represents a different item. Vertices also store the support information related to the itemset comprising all of the items on the path from the root to a given vertex. To build the FP-tree, we start with a tree containing the null item $\emptyset$ as root. For each transaction $T_i \in \mathcal{D}$, the itemset T_i is inserted into the FP-tree, and the count of all of the vertices along the path representing T_i is incremented. When T_i shares a common prefix with some previously inserted transaction, T_i will follow the same path until the common prefix. Regarding the remaining items in T_i , new vertices are inserted under the common prefix, and their count is initialized to 1. The FP-tree construction is complete when all of the transactions have been processed and inserted.

The usefulness of the FP-tree lies in being a prefix compressed representation of the database $\mathcal{D}$. In order to compact the FP-tree as much as possible, so that the most frequent items are found at the top, near the root, the algorithm reorders the items in decreasing order of support. Starting from the initial database, FP-growth determines the support of all of the single items $i \in \mathcal{U}$. Then, infrequent items are discarded, and frequent items sorted by decreasing support. Finally, each transaction $T_i \in \mathcal{D}$ is inserted into the FP-tree after reordering T_i by decreasing item support.

The algorithm now uses the FP-tree as an index in place of the original database. The frequent itemsets are mined from the tree as shown in Algorithm 3. The algorithm takes as input a FP-tree R built from the database $\mathcal{D}$, and the current itemset prefix P , which is initially empty.

FP-GROWTH builds projected FP-trees for each frequent item i in R in increasing order of support. The projection of R on item i is determined by finding all of the occurrences of i in the tree, and for each occurrence, computing the corresponding path from the root to i . The count of each item i on a given path, is stored in the variable $cnt(i)$. The path is then inserted into the new projected tree RX , where X is the itemset obtained by extending the prefix P with the item i .

Algorithm 1: *Apriori* algorithm

Input: $\mathcal{D}$, a database of transactions; U , a universe set of items; $minsup$, the minimum support

Output: the set $\mathcal{L}$ of frequent itemsets in $\mathcal{D}$

```

1  procedure APRIORI( $\mathcal{D}, U, minsup$ )
2     $\mathcal{L}_1 \leftarrow \text{FIND\_FREQUENT\_ITEMS}(\mathcal{D}, minsup)$ 
3     $k \leftarrow 2$ 
4    while  $\mathcal{L}_{k-1} \neq \emptyset$  do
5       $C_k \leftarrow \text{APRIORI\_GEN}(\mathcal{L}_{k-1})$ 
6      foreach transaction  $t \in \mathcal{D}$  do
7        foreach candidate  $c \in C_k$  do
8          if  $c \subset t$  then
9             $sup(c) \leftarrow sup(c) + 1$ 
10         end
11       end
12     end
13      $\mathcal{L}_k \leftarrow \{c \in C_k \mid sup(c) > minsup\}$ 
14      $k \leftarrow k + 1$ 
15   end
16    $\mathcal{L} \leftarrow \cup_k(\mathcal{L}_k)$ 
17   return  $\mathcal{L}$ 
18 end

19 procedure APRIORI_GEN( $\mathcal{L}_{k-1}$ )
20   foreach  $l_1 \in \mathcal{L}_{k-1}$  do
21     foreach  $l_2 \in \mathcal{L}_{k-1}$  do
22       if  $l_1$  and  $l_2$  share the first  $k - 2$  items and  $l_1[k - 1] < l_2[k - 1]$  then
23          $c \leftarrow l_1 \cup l_2$ 
24         if HAS_INFREQUENT_SUBSETS( $c, \mathcal{L}_{k-1}$ ) then
25           // if the candidate has a  $(k - 1)$ -subset that is not in  $\mathcal{L}_{k-1}$  discard it
26           discard  $c$ 
27         else
28            $C_k \leftarrow C_k \cup c$ 
29         end
30       end
31     end
32   return  $C_k$ 
33 end

```

Algorithm 2: *Eclat* algorithm**Input:** a vertical database of transactions; *minsup*, the minimum support**Output:** the collection of frequent itemsets in $\mathcal{F}$ // Initial call: $\mathcal{F} \leftarrow \emptyset, P \leftarrow \{(i, T(i)) : i \in \mathcal{U}, |T(i)| \geq \text{minsup}\}$

```

2   foreach  $(X_a, T(X_a)) \in P$  do
3      $\mathcal{F} \leftarrow \mathcal{F} \cup \{(X_a, \text{sup}(X_a))\}$ 
4      $P_a \leftarrow \emptyset$ 
5     foreach  $(X_b, T(X_b)) \in P$ , with  $X_b > X_a$  do
6        $X_{ab} \leftarrow X_a \cup X_b$ 
7        $T(X_{ab}) \leftarrow T(X_a) \cap T(X_b)$ 
8       if  $\text{sup}(X_{ab}) \geq \text{minsup}$  then
9          $P_a \leftarrow P_a \cup \{(X_{ab}, T(X_{ab}))\}$ 
10      end
11    end
12    if  $P_a \neq \emptyset$  then
13      ECLAT( $P_a, \text{minsup}, \mathcal{F}$ )
14    end
15  end
16 end

```

Algorithm 3: FP-GROWTH algorithm**Input:** $\mathcal{D}$, a database of transactions; *minsup*, the minimum support**Output:** the collection of frequent itemsets in $\mathcal{F}$ // Initial call: $R \leftarrow \text{FP-tree}(\mathcal{D}), P \leftarrow \emptyset, \mathcal{F} \leftarrow \emptyset$

```

1 procedure FP-GROWTH( $R, P, \mathcal{F}, \text{minsup}$ )
2   Remove infrequent items from  $R$ 
3   if ISPATH( $R$ ) then                                     // insert subsets of  $R$  into  $\mathcal{F}$ 
4     foreach  $Y \subseteq R$  do
5        $X \leftarrow P \cup Y$ 
6        $\text{sup}(X) \leftarrow \min_{x \in Y} \{\text{cnt}(x)\}$ 
7        $\mathcal{F} \leftarrow \mathcal{F} \cup \{(X, \text{sup}(X))\}$ 
8     end
9   else                                                     // process projected FP-trees for each frequent item  $i$ 
10    foreach  $i \in R$  in increasing order of  $\text{sup}(i)$  do
11       $X \leftarrow P \cup \{i\}$ 
12       $\text{sup}(X) \leftarrow \text{sup}(i)$                                // sum of  $\text{cnt}(i)$  for all of the nodes labeled  $i$ 
13       $\mathcal{F} \leftarrow \mathcal{F} \cup \{(X, \text{sup}(X))\}$ 
14       $R_X \leftarrow \emptyset$                                    // projected FP-tree for  $X$ 
15    end
16  end
17  foreach  $\text{path} \in \text{PATHFROMROOT}(i)$  do
18     $\text{cnt}(i) \leftarrow \text{count of } i \text{ in path}$ 
19    Insert  $\text{path}$ , excluding  $i$ , into FP-tree  $R_X$  with count  $\text{cnt}(i)$ 
20  end
21  if  $R_X \neq \emptyset$  then
22    FP-GROWTH( $R_X, X, \mathcal{F}, \text{minsup}$ )
23  end
24 end

```

When a path is inserted, the count of each vertex in RX along the given path is incremented by the corresponding path count $cnt(i)$. The item i is omitted from the path, since it now belongs to the prefix. The derived FP-tree is the projection of the itemset X that includes the current prefix extended with item i . The algorithm is then recursively invoked with projected FP-tree RX and the new prefix itemset X as input parameters. The recursion ends when the input FP-tree R is just a single path. In this case, all of the itemsets that are subsets of the path are enumerated, and the support of each such itemset is determined by the least frequent item in it.

Conclusions

We presented an overview of a fundamental data mining task, the mining of frequent itemsets and association rules of large data sets. We started with an introduction to the problem in the more general context of data mining and a sample of its possible applications. Then, we reviewed the basic concepts and definitions regarding frequent itemset mining and the main interestingness measures of the usefulness and informative capacity of association rules. At last, we described some of the most important classical algorithms that deal with frequent itemset mining.

Association Rules and Frequent Patterns

Giuseppe Di Fatta, University of Reading, Reading, United Kingdom

Introduction

Association Rule Mining (ARM) (Agrawal *et al.*, 1993; Agrawal and Srikant, 1994; Hipp *et al.*, 2000) is often referred to as frequent pattern mining (Goethals, 2003; Han *et al.*, 2007; Aggarwal and Han, 2014; Fournier-Viger *et al.*, 2017). Frequent pattern mining focuses on the extraction of the frequent patterns, ARM also offers a specific and more descriptive representation of the frequent patterns in the form of association rules: If the pattern X is present, then also the pattern Y is. Anyway, since ARM relies on the extraction of the frequent patterns, which is a particularly complex task, the two are often considered equivalent, at least, from the computational point of view. In the most common formulation of the ARM problem, patterns take the form of sets and, more specifically, of sets of items (itemsets). An item is a binary feature, such as the presence of a specific attribute or property. In general, ARM is applied to extract and explicitly represent events (attributes) that occur together in the data and more frequently than others. The assumption is that events that frequently occur together are more important of those not occurring together or not frequently enough. For example, in market basket analysis the itemset is the set of items purchased by a customer within a single transaction. The interesting relations to be exposed are the explicit or implicit associations made by customers in emerging shopping behaviours.

In the life sciences the adoption of ARM to address some data-intensive problems (Atluri *et al.*, 2009) did not receive the same attention as for other statistical and data mining techniques, such as correlation, regression, classification and clustering. However, since the widespread adoption of genomic sequencing and other high-throughput digital technologies, very large datasets have become more common and often publicly available. For example, mining association rules in genomic data (Hanash, 2003; Alves *et al.*, 2010; Oellrich *et al.*, 2014; Chen *et al.*, 2015) has become of more interest and adopted for two main tasks: identifying the significant patterns in subsets of genes and between gene regulation and phenotype.

Specific domain knowledge is useful to understand if the representation of the itemsets as binary attributes may force an undesired asymmetric semantics. The presence of an attribute in a sample is encoded by the presence of an item in the itemset: the item typically has an explicit positive meaning. The lack of an attribute often is not significant and is not explicitly encoded in the itemset. However, when this is not the case and the lack of some attribute is of interest, a specific 'negative' item can be used to encode this information explicitly in the itemsets. Alternatively Negative Association Rules (Antonie and Zañane, 2004) can be applied to extract relations, for example, between the absence of an item and the presence of others.

Arguably some limiting factors have hindered a more widespread adoption of ARM. Firstly, the discovery of interesting patterns from data requires complex combinatorial algorithms and often these benefit from high performance computing. For real-world problems the search space may be prohibitively large. Secondly, it is not uncommon that even for a relatively small input dataset, the set of discovered patterns is very large, even larger than the input dataset. In this case ARM is only a first step in more complex data workflows that include other data mining techniques. For these reasons, a multidisciplinary approach that combines expertise from both computer science and the specific application domain is often critical.

The rest of the article is organised as follows. Section "Problem Definition" introduces the basic ARM problem and discuss the combinatorial nature of the computational task. Some important ARM algorithms, the search space of patterns and some interestingness criteria are presented in Section "ARM Algorithms". Some extended ARM problems are briefly reviewed in Section "Extended Association Rule Mining" and, finally, Section "Conclusions" provides some conclusive remarks.

Problem Definition

Consider a set of binary attributes $\mathcal{I} = \{A, B, C, \dots\}$ ($|\mathcal{I}| = d$) called items. A proper subset $s \subset \mathcal{I}$ is referred to as *itemset*. A k -itemset s is an itemset of k items, i.e., $|s| = k$. A transaction over $\mathcal{I}$ is a pair $t = \langle id, s \rangle$, where id is the transaction identifier and s is an itemset. $\mathcal{T}$ is the set of transactions ($|\mathcal{T}| = n$), a transactional database. A transaction $t = \langle id, s \rangle$ is said to support an itemset x , if $s \supseteq x$. For example, the transaction $\langle 0F36A, \{BCDH\} \rangle$ supports the itemset $\{BD\}$ and it does not support the itemset $\{BDE\}$. The support σ of an itemset x is the fraction of transactions that support x , i.e., $\sigma(x) = \frac{|\{ \langle id, s \rangle \in \mathcal{T} : s \supseteq x \}|}{n}$.

An association rule (Agrawal and Srikant, 1994) is an implication expressed in the form $X \Rightarrow Y$ (" X implies Y ", " X then Y "), where X and Y are itemsets ($X, Y \subset \mathcal{I}$) with $X \cap Y = \emptyset$. The left term is referred to as the antecedent, the right term as the consequent of the rule. The 'support' of a rule is the fraction of transactions that support $X \cup Y$, which corresponds to the empirical joint probability $P(X \cup Y)$.

$$\text{support}(X \Rightarrow Y) = \sigma(X \cup Y) \quad (1)$$

The 'confidence' of a rule is the fraction of transactions supporting X that also support Y . The confidence of a rule corresponds to the empirical conditional probability $P(Y|X)$.

$$\text{confidence}(X \Rightarrow Y) = \frac{\sigma(X \cup Y)}{\sigma(X)} \quad (2)$$

A rule is said 'frequent', if it is supported by at least a minimum fraction of transactions in $\mathcal{I}$. A user-defined parameter for the minimum support (*minsup*) is required for this purpose. A rule is said 'strong', if it has a confidence greater or equal to a user-defined parameter *minconf*.

Given a transactional database $\mathcal{I}$ and two user-defined parameters *minsup* and *minconf*, the Association Rule Mining problem is to find all frequent and strong rules.

$$\begin{aligned} X \Rightarrow Y, \quad \text{where } X, Y \subset \mathcal{I}, \quad X \cap Y = \emptyset, \\ \sigma(X \cup Y) \geq \text{minsup} \quad \text{and} \quad \frac{\sigma(X \cup Y)}{\sigma(X)} \geq \text{minconf} \end{aligned} \quad (3)$$

The Search Space

The search space of the ARM problem is limited by all possible combinations for the antecedent and the consequent of a rule. The total number of itemsets is the cardinality of the power set, $|\text{Power}(\mathcal{I})| = 2^d$.

Although the disjoint constraint reduced the number of possible combinations, they are still expected to be exponential in the number d of items. The total number R of possible association rules is given by all possible itemset combinations for the antecedent times all possible itemset combinations for the consequent, as expressed by Eq. (4). There are $\binom{d}{k}$ possible k -itemsets as antecedent and, given a k -itemset as antecedent, there are $\binom{d-k}{j}$ possible j -itemsets as consequent.

The total number R of possible association rules is given by

$$R = \sum_{k=1}^{d-1} \left[\binom{d}{k} \cdot \sum_{j=1}^{d-k} \binom{d-k}{j} \right] = 3^d - 2^{d+1} + 1 \quad (4)$$

where the following equation derived from the binomial theorem has been applied for the reduction of the expression.

$$\sum_{k=0}^m \binom{m}{k} \cdot r^k = (1+r)^m \quad (5)$$

For example, a set of 10 items generates 57,002 rules; while 20 items generate almost 3.5 billion rules. Obviously a brute force approach that enumerates all possible rules and validates them against the minimum support and confidence constraints, is not a feasible solution to the ARM problem.

The computational complexity of the problem with binary attributes and its other variants (e.g., a quantitative approach) has been shown to be NP-complete (Wijzen and Meersman, 1998; Yang, 2004; Angiulli et al., 2001). The challenging combinatorial nature of the problem has given rise to an intense research (Agrawal et al., 1993; Agrawal and Srikant, 1994, 1986; Hipp et al., 2000; Zaki et al., 1997; Savasere et al., 1995; Toivonen, 1996; Brin et al., 1997; Han et al., 2000) and a number of efficient algorithms, the more representative of which are briefly reviewed in the next section.

ARM Algorithms

The observation that the computation of the support of the rule $\sigma(X \cup Y)$ is necessary in both constraints (Eqs. (1) and (2)) suggests an efficient problem decomposition into two sub-problems, which was originally introduced in the *Apriori* algorithm (Agrawal and Srikant, 1994).

1. Find all Frequent Itemsets (FI):

$$FI = \{x | x \subset \mathcal{I} \quad \text{and} \quad \sigma(x) \geq \text{minsup}\}$$

2. Generate all strong rules from FI.

In the second step only the confidence of the rules has to be tested, as any rule generated from the FI set is guaranteed to have sufficient support. The second problem can be solved by a straightforward polynomial time algorithm and most of the computational complexity lies in the first problem. All the possible itemsets correspond to the powerset $\mathcal{P}(\mathcal{I})$, where $|\mathcal{P}(\mathcal{I})| = 2^d$. This is still an exponential search space, though $3^d - 2^{d+1} + 1 > 2^d$ for $d > 2$, and it requires efficient combinatorial algorithms, optimisation techniques, high performance computing and, ultimately, additional domain-specific constraints to limit the search space.

The powerset $\mathcal{P}(\mathcal{I})$ can be represented as a lattice of sets. For example, Fig. 1 shows the lattice of all possible itemsets for a set of four items, which are represented as natural numbers ($\mathcal{I} = \{1, 2, 3, 4\}$). The binomial coefficients on the left indicates the number of subsets at each tier of the lattice and the edges indicate a subset-superset relation between itemsets in consecutive tiers. Fig. 2

Fig. 1 Lattice of itemsets: Powerset for $\mathcal{I}=\{1,2,3,4\}$ ($d=4$).

Fig. 2 Border between frequent and infrequent itemsets: The number in the circle indicates the support of the itemset.

provides an example of the border of the frequent itemsets for the transactions listed in the table and for a minimum support of 3 transactions (50%).

The main algorithmic strategy is to generate candidate frequent itemsets and test their support efficiently and without any redundancy, considering the computing system limitations. In most real-world applications the search space is too large to fit in main memory. Moreover, in spite of the exponential complexity optimisation techniques can provide a sufficient run time efficiency to tackle problems large enough to be of interest.

To this aim a number of optimisation techniques have been proposed, which refer to the strategy of visiting the lattice (breadth vs depth first), to the generation of the candidate itemsets, and to the data structure and the algorithm for testing the constraint of the minimum support of candidate itemsets.

In particular, one fundamental optimisation technique is based on the anti-monotonicity (or downward-closure) property of the support. Any superset of an itemset cannot have a support greater than its subset. In Fig. 2, the infrequent itemsets are highlighted in grey: the edges from them moving forward to the next tier are represented as dashed lines to indicate that their supersets are implicitly, a priori, known to fail the support constraint. The algorithm *Apriori* (Agrawal and Srikant, 1994) was the first to introduce and exploit these concepts with the so-called *Apriori* ‘pruning’ optimisation.

Among the many algorithms proposed in the last two decades or so, three of them have a particular importance as each introduced a specific novel approach that inspired many others. The algorithm *Apriori* (Agrawal and Srikant, 1994) adopts a breadth-first strategy by generating the itemsets of a single tier at a time. The algorithm *Eclat* (Zaki, 2000) adopts the opposite depth-first strategy reducing the memory requirements. The algorithm *FP-growth* (Han et al., 2000) also adopts a depth-first search and introduced a clever tree-based data structure to improve the running time significantly.

Efficient implementations of algorithms for mining frequent itemsets are available as executable or source code (Borgelt, 2003, 2012, 2017), or by means of extensions of data science development environments, such as *arules* (Hornik et al., 2005), which is an R package for generating, managing and analysing frequent itemsets and association rules.

Interestingness Measures and Criteria

Interesting correlations among items and itemsets in patterns and association rules may not always be represented only by frequency (support and confidence). For example, the support does not consider normalisation of the frequencies of the items and may be skewed towards highly frequent items. Moreover, when patterns are considered interesting only on their frequency, the number of discovered patterns is often very large with a significant redundancy.

For these reasons other interestingness criteria and measures have also been considered. In some cases additional domain-specific measures can be used for ranking the patterns and prioritise their analysis. In others, pruning unnecessary and redundant patterns is a possible approach.

In applications of frequent itemset mining, the user typically applies an exploratory and iterative approach starting from large values of the support threshold (*minsupp*). Such large values of *minsupp* are chosen so that the number of frequent itemsets is small. Unfortunately, this often leads to frequent itemsets of small size, which may not be particularly interesting. Hence, in order to find more interesting frequent itemsets, the support threshold needs to be set to smaller values, for which the number of the frequent itemsets can be quite large, possibly too large for user inspection and analysis.

It turns out that some of the frequent itemsets may not be of particular interest as they have identical support as their supersets. For example, consider the two frequent itemsets 3 and 13 in Fig. 2, they are supported by the same three transactions (*id* = 1, *id* = 4 and *id* = 6). In this case, the frequent itemset 13 is ‘maximal’ within the three supporting transactions, while 3 is not.

Following this consideration, a method of reducing the large amount of frequent itemsets is to use one of the so-called compact or condensed representations, such as the Maximal Frequent Itemsets (MFI) and the Closed Frequent Itemsets (CFI) (Uno et al., 2004).

MFI are frequent itemsets for which none of their supersets is also frequent. Clearly, any frequent itemset is a subset of a maximal frequent itemset. In other words, a frequent itemset is maximal if it is not a proper subset of any other frequent itemset.

A frequent itemset is closed if it contains all items that occur in all transactions in which it is bought, i.e., it is the intersection of its supporting transactions. In other words, a closed frequent itemset is a frequent itemset whose support is higher than the supports of all its proper supersets. In particular, all maximal frequent itemsets are also closed.

The underlying idea of both definitions is that the set of all maximal or closed frequent itemsets can be used as a compact representation of all frequent itemsets: It can be seen as a form of compression.

The set MFI allows to reconstruct all frequent itemsets by simply generating all their subsets. However, the support of these subsets cannot be reconstructed: the support of a frequent itemset can be different from the support of its maximal itemset. An additional database scan is needed to reconstruct this information, if necessary. MFI can be seen as a form of compression with loss of information.

This issue is overcome with the set CFI. The support of a non-closed itemset is the support of the smallest superset that is closed. CFI can be seen as a form of compression without loss of information.

Many other sampling criteria and definitions for subsets of frequent itemsets have also been proposed and include free frequent itemsets (Boulicaut et al., 2003), non-derivable itemsets (Calders and Goethals, 2007) and margin-closed frequent itemsets (Moerchen et al., 2011).

If the number of itemsets in a condensed subset is still too large for a manual analysis, then other data mining techniques can be applied to the complete set of frequent itemsets, or one of its subsets, in order to generate a model or a view at a higher level of abstraction (e.g., (Di Fatta et al., 2006)).

Extended Association Rule Mining

The basic concept of mining association rules and frequent patterns can be extended in a number of ways in order to gain more generality or to account for other attribute types (e.g., numerical or temporal attributes) in the data.

Generalised Association Rules (Sarawagi and Thomas, 1998) adopt a hierarchical taxonomy (concept hierarchy) of the items. Considering that coke and pepsi are soft drinks and assuming they are frequently bought with chips, nuts or crackers, a generalised rule may be express that “60% of transactions that contain soft drinks also contain snacks”.

Quantitative Association Rules (Srikant and Agrawal, 1996) considers both quantitative and categorical attributes in the data. For example, the rule “10% of married people between age 50 and 60 have at least 2 cars” is able to associate a qualitative attribute with a quantitative one. In Interval Data Association Rules (Miller and Yang, 1997) the range of quantitative attributes is partitioned: For example, age can be partitioned into 5-year-increment intervals.

Mining Maximal Association Rules and Closed Association Rules (Uno *et al.*, 2004) directly discovers the condensed subsets of the frequent itemsets, as discussed in Section “Interestingness Measures and Criteria”.

Sequential Association Rules (Sarawagi and Thomas, 1998) consider temporal data and discover subsequences: For example, users frequently buy first a PC, then a printer and, finally, a digital camera. Sequential pattern mining (Mabroukeh and Ezeife, 2010) can be applied to a variety of domains where the order of the items is relevant, e.g., Web log data and DNA sequences (Abouelhoda and Ghanem, 2010).

In Frequent Subgraph Mining (Kuramochi and Karypis, 2001) the data in the transactions are in the form of graphs. These may include many types of networks, such as social networks, protein-protein interaction networks (Shen *et al.*, 2012) and molecular compounds (Deshpande *et al.*, 2002). Finding frequent subgraphs in a set of graphs involves graph and subgraph isomorphism testing, which is more complex than subset testing required in frequent itemsets mining, and efficient and parallel computing approaches may be required for large datasets (Di Fatta and Berthold, 2005, 2006).

ARM Applications

Association rule and, in general, frequent pattern mining was originally inspired and motivated by market basket and customer behaviour analysis (Agrawal *et al.*, 1993; Agrawal and Srikant, 1994) and over the last two decades it has been successfully applied to many other applications domains. Various applications have been developed initially in other computer science fields, such as software bug discovery, failure and event detection in telecommunication and computer networks, WWW user behaviour analysis, and later in multidisciplinary domains including bioinformatics, chemoinformatics and data-driven medical applications.

Arguably the most popular example of association rules was extracted from supermarket transactions to reveal buying behaviour of customers: $IF\{DIAPERS\} \Rightarrow \{BEER\}$. This alleged association rule is often used to underline the nature of the correlations emerging from data: there is no implication of causality, only co-occurrence. The goal of ARM is to systematically extract all frequent and strong rules with an empirical (data-driven) approach. Domain experts may be able to gain useful insights from the generated rules and use them to support decision making, for example, in shelf management, marketing and sale promotions. The true story behind the example of diapers and beer is that in 1992, a retail consulting group at Teradata analysed 1.2 million customer transactions from Osco Drug stores. SQL self joins queries, not ARM, were used to identify correlations between (expensive) baby's products and any other product. The analysis discovered that between 5 and 7 p.m. consumers often bought diapers and beer. Apparently no attempt was made to exploit this correlation: Beers were not relocated near diapers. Nevertheless, this unexpected correlation raised much attention in the data analytics and mining community, and inspired a stream of research on association rules.

In telecommunication and computer networks, sequential pattern mining can be applied to the detection of events and anomalies (Cui *et al.*, 2014), to the analysis of user behaviour from Web logs (Pei *et al.*, 2000) and of online social media content (Adedoyin-Olowe *et al.*, 2013).

Detection of software bugs is another interesting example of ARM applications. Errors and faults leading to unexpected results, i.e., non-crashing bugs, is a difficult case of software bug detection (Liu *et al.*, 2005). For example in (Fatta *et al.*, 2016), function calls are recorded during software test executions and are analysed with a frequent pattern mining algorithm. Frequent subgraphs in failing test executions that are not frequent in successful test executions are used to rank the functions according to their likelihood of containing a fault.

Frequent pattern mining has been applied to biological data (Rigoutsos and Floratos, 1998) as these may come in the form of sequences (e.g., Microarray data (Cong *et al.*, 2004, 2005) and RNA (Chevalet and Michot, 1992)) and graphs (e.g., protein-to-protein interaction networks (Cho and Zhang, 2010), phylogenetic trees (Shasha *et al.*, 2004), molecular compounds (Di Fatta and Berthold, 2005, 2006; Deshpande *et al.*, 2005)).

In real-world applications frequent pattern and association rule mining is often one step in a more complex data analytics workflow, which may include other data mining techniques, such as classification and clustering, and data visualisation. The set of discovered patterns or rules can even be larger than the input dataset and a direct user inspection is not feasible, nor desirable. In some cases, frequent pattern mining can be seen as a feature generation step in the knowledge discovery process. For example, in (Di Fatta *et al.*, 2006) the frequent patterns are used to identify candidate drugs for a target activity and are considered as attributes in a very high dimensional space. A self-organising map is used to generate a 2-dimensional map of drugs, where proximity in the map indicates that activity against a target disease is due to a similar molecular substructure.

Conclusions

This article provides a brief survey of association rule and frequent pattern mining, which is one of the most important method in data mining for data-driven scientific discovery. A large body of literature has been produced in the past two decades or so. From the early introduction of the problem definition and the algorithms for market basket analysis, more efficient methods, extended

problem definitions, advanced interestingness criteria and a plethora of applications in many diverse domains are nowadays available. In particular, the application domains have gradually expanded to cover a wide range, including software engineering, computer networks, bioinformatics, chemoinformatics and many other life sciences and scientific domains.

A general problem definition is presented and the combinatorial complexity of the computational task discussed. In particular, the exact exponential number of possible rules that are implicitly defined by a set of items is derived. Some of the most relevant algorithms, the fundamental and advanced interestingness criteria are presented. The most relevant extended problems and some application domains are also discussed with examples.

ARM is arguably one of the most elegant data mining problems that has fascinated the data mining community for many years and has a great potential to contribute to many scientific domains. It can provide a formidable tool for exploratory investigations to reveal intriguing insights from data, and ultimately lead to unexpected data-driven scientific discoveries.

Introduction

Technological advancements of the last decades sparked an explosion in the amounts of data acquired in several scientific fields. In particular, high-throughput technologies have lead to an incredible growth of biological data. It is not uncommon, for instance, to measure simultaneously the levels of expression of thousands of genes thanks to microarray and sequencing technologies. As a natural consequence, several specialized databases accessible through the Internet have been populated. However, this data needs to be converted into knowledge to allow scientific progress. Machine Learning models allow to study the interactions among variables of interest, and have been employed in various scientific fields, including bioinformatics. Here, we review the theoretical and practical foundations of Decision Trees and Random Forests, as well as recent work from literature.

Before going on, we introduce the notation that we will use throughout this article. To keep the exposition clear, here, we focus on the context of classification problems. However, decision trees and random forests are flexible enough to be applied to regression problems, as well as to unsupervised learning. For an in depth discussion we will refer to the bibliographic references and to the additional resources useful for the interested reader at the end of this article.

Notation

The i -th observation of a dataset of samples is represented by the vector of its features, or variables, denoted by $\mathbf{x}_i$, and its dimensionality, i.e., the number of features, denoted by p .

The value of the j -th feature of the observation $\mathbf{x}_i$ is denoted by $x_{i,j}$, whereas we refer to the vector of all the values of a single feature as $\mathbf{x}_{:,j}$.

The outcome variable, or experimental condition or class label, corresponding to the observation $\mathbf{x}_i$ is represented by y_i which, in case of classification problems, is a discrete variable that can assume a finite number of different values, each corresponding to a different class.

A whole dataset is denoted by the $n \times p$ matrix X obtained by stacking all the feature vectors, where n is the number of samples of the dataset.

Similarly, the n dimensional vector of outcomes, denoted by $\mathbf{y}$, is obtained by concatenating the outcome values of each observation of the dataset.

Decision Trees

Decision trees are models based on the principle of *divide et impera*, i.e., the training dataset is recursively partitioned into non-overlapping rectangular regions (multi-dimensional boxes) and each derived region is associated with a decision rule responsible for the classification of that region.

This partitioning has the advantage of not limiting the relationship between the outcome variable (e.g., the class label of a sample) and the input variables (e.g., the features of a sample) of the dataset to a particular function family, like, for example, a linear relationship for Discriminant Analysis. These models are called non-parametric and their major strength is to automatically tune the complexity of the learned relationship directly from the data (Breiman *et al.*, 1984).

The resulting partitioning scheme can be represented by a binary tree as in Fig. 1. On the left, an artificial non-linearly separable dataset fitted with a decision tree is shown. On the right, the trained classifier is represented as a binary tree. Predictions can be performed by visiting the tree and performing the tests included inside the diamond shaped nodes. When a rectangular node is reached, the predicted label corresponds to the reported class.

A fitted decision tree can also be visualized as a set of intelligible decision rules. Each path from root to a leaf node can be translated into a chain of "IF-THEN" conditions that can be applied to observations to classify them. This makes decision trees particularly valuable in life sciences, where the inspection of decision rules can bring insights about the experimental question.

Training Algorithm

The general algorithm for training a decision tree involves two main phases: a growing phase and an optional pruning phase. In the growing phase, the decision tree is built in a top-down fashion. Starting with the whole dataset corresponding to the root node of the tree, a feature and a split value are identified according to a splitting criterion and the dataset is partitioned into two disjoint subsets depending on that feature value. This procedure is then recursively performed to each subset, until a stopping condition is reached.

Fig. 1 Left: A two-classes synthetic dataset non-linearly separable. Right: The corresponding fitted classifier represented as a decision tree.

After growing, the tree may become too complex compared to the size of the training dataset. The optional pruning phase is used to avoid, or at least reduce, overfitting issues. In this case, each node is evaluated by a pruning criterion. When a node satisfies the pruning condition, its sub-tree is removed and the corresponding node becomes a leaf node. Pruning a sub-tree corresponds to merging together subsets of the training dataset. This procedure goes on until the tree is reduced to a single node and the best (in terms of accuracy) sub-tree built during the process is kept as the final tree. Lastly, each region of the dataset, represented by a leaf node, is associated with a decision rule, which usually corresponds to assign the most frequent class label in the corresponding region to the observations belonging to it (Breiman *et al.*, 1984).

Splitting criteria

During each step of the growing phase, the training procedure finds a feature $x_{i,j}$ and a split value s to divide the current set of observations X' into two smaller and more pure (or coherent) subsets $S_1 = \{x_i : |x_{i,j}| \leq s\}$ and $S_2 = \{x_i : |x_{i,j}| > s\}$.

Common purity criteria for classification problems are the Gini index and the Cross-entropy index:

$$\sum_{k=1}^K \hat{p}_k (1 - \hat{p}_k) \quad \text{Gini index}$$

$$\sum_{k=1}^K \hat{p}_k \log \hat{p}_k \quad \text{Cross entropy index}$$

Where $\hat{p}_k$ is the fraction of samples of each class k associated to a given subset S_i . Both indexes, equal 0 when $\hat{p}_k = 0$ or $\hat{p}_k = 1$ and reach the maximum value when $\hat{p}_k = \frac{1}{2}$ meaning that homogeneous subsets with the same value of the outcome variable (class label) are preferred.

Stopping criteria

Clearly, it is not possible to have more leaf nodes than samples in the training set. This configuration also corresponds to maximally pure leaf nodes. However, in this case, generalization performances to new samples will be poor. To avoid the explosion of the tree complexity, the growing phase must be stopped early in some nodes.

Common stopping criteria include limiting the minimum number of samples per node or the minimum level of impurity to split a node.

Pruning criterion

In Breiman *et al.* (1984) it was observed that imposing tight stopping criteria leads to underfit trees. On the other hand, training an unrestricted decision tree and then pruning it with the weakest link pruning procedure is shown to improve generalization performances.

The weakest link pruning procedure goes in the opposite direction of training: starting with the full tree, a sequence $T_0, T_1, \dots, T_k$ of smaller and smaller trees is built, where T_0 is the full tree and T_k is the tree with a single node. Each sub-tree T_{i+1} is built by collapsing each internal node of the sub-tree T_i into a leaf node, one at a time, and evaluating the error rate increase over the pruned leaves:

$$\alpha = \frac{\text{err}(T_{i+1}, \mathbf{X}') - \text{err}(T_i, \mathbf{X}')}{\text{leaves}(T_i) - \text{leaves}(T_{i+1})}$$

where $\text{err}(T, \mathbf{X}')$ is the error rate of tree T on the set of observations $\mathbf{X}'$, and $\text{leaves}(T)$ corresponds to the number of leaves for tree T . After the evaluation of all the collapsed sub-trees of T_i , the sub-tree that gets the lowest value of α is taken as T_{i+1} . The criterion α is also known as complexity parameter as it is used to determine the appropriate amount of complexity (the total number of leaves) to preserve from the original tree.

Finally, the optimally pruned tree is chosen from the sequence evaluating the performance of each sub-tree on a pruning dataset, not used during the training of T_0 . When data is not enough to be split into training and pruning datasets, cross-validation procedures can be used instead, although at a higher computational cost.

Random Forests

Despite the success and the desirable properties of decision trees, their discrete nature implies high variance in predictions, especially along the decision boundary. This means that small perturbations on the training dataset, may induce wild variations in predictions.

A Random Forest is an ensemble method based on bagging (bootstrap aggregating) (Breiman, 1996) where a large set of unstable (i.e., with high variance in predictions) but independent classifiers are aggregated using a majority vote to produce a more accurate classification with respect to each single model. The base predictor structure used in Random Forests is the decision tree, hence the name.

Ensemble learning methods allow constructing models that produce better predictions taking aggregations of predictions from a set of individual classifiers (Dietterich, 2000).

Two necessary assumptions for the ensemble model to be more accurate than its individual models are that (1) each of them must be more accurate than random guessing and (2) they need to produce as much independent errors as possible, i.e., there is some type of relation between the errors made by different classifiers in the ensemble.

In fact, an accuracy even slightly higher than random guess is sufficient to guarantee that the probability that the whole ensemble predicts the wrong class is reduced. The independence of errors is needed to ensure that possible wrong predictions are rejected by the rest of the classifiers which are expected to be higher in number, thereby increasing the overall accuracy.

More formally, consider an ensemble made of an odd number c of perfectly independent binary classifiers (i.e., there is not any statistical relation between the predictions of different classifiers), where each classifier has an error rate (i.e. probability of making a wrong prediction) of $p < \frac{1}{2}$. The ensemble then produces a wrong prediction when at least $\frac{c-1}{2} + 1$ individual classifiers are wrong, this happens with probability $(\frac{c-1}{2} + 1)^p + (\frac{c-1}{2} + 2)^p + \dots + (c)^p$, and this probability decreases very fast with an increasing number of classifiers.

As an example, let us consider an ensemble of 11 perfectly independent binary classifiers, each with a probability of error of $p = 0.499$, the probability that the whole ensemble is wrong drops to 0.03. Thus, even though the performance of each single classifier is near the random guess, ensembling even a small amount of independent classifiers will greatly improve the global performance.

Care must be taken since the above example is an ideal case and the computed probability is actually a lower bound. In practical applications, predictions within the ensemble are hardly perfectly independent. Nonetheless, good performances can be achieved, in practice, by maximizing the independency between the trained decision trees within the random forest.

Bagging and Random Subspace Selection

To enforce independency between predictors, the most common techniques are (Dietterich, 2000):

1. Train each predictor on a different subset of the original set of training samples.
2. Train each predictor on a different subset of features of the original training data.
3. Train different classes of predictors.

In Random Forests, independence among the predictors is ensured by training each of them on a bootstrapped training dataset, i.e., resampled with replacement from the original dataset and with the same number of samples. Also, to increment the

randomness needed to reduce dependencies between predictors in the ensemble, the search for the best split is performed each time on a different random subset of features of the dataset (Breiman, 2001).

The random selection of a subset of features has also the advantage of reducing the susceptibility of random forests to the curse of dimensionality, i.e., by considering only a few features at a time, the random forest is more robust to the noisy features in high-dimensional datasets, like gene expression datasets.

Out of Bag Error Estimate

When building the bootstrap dataset for each decision tree, each observation in the original dataset has a probability of $(1 - \frac{1}{n})^n$ of not appearing in a given bootstrapped dataset. In particular, this probability tends to $\frac{1}{e} \approx 0.3679$ as n increases, where n is the number of observations in the original dataset. This means that each decision tree is trained on a dataset that, on average, contains roughly two thirds of the observations in the original dataset, whereas the remaining are replicated observations.

Since each decision tree of the ensemble is trained on a bootstrapped dataset, then there is a set of approximately one third of samples belonging to the original dataset, different for each tree, and that is not used for training. Thus, it can be used to estimate the generalization performance of the tree. The generalization estimates of all trees of the ensemble are aggregated by averaging into the Out Of Bag (OOB) error estimate of the ensemble.

Through the OOB error, it is possible to estimate the generalization capabilities of the ensemble without the need of an hold-out test set (Breiman, 1996) that would be otherwise necessary as for any other machine learning model not based on a bagging mechanism.

Empirical studies showed that the OOB error is as accurate in predicting the generalization accuracy as using a hold-out test set given a sufficient number of estimators in the forest to make the OOB estimate stable (Breiman, 2001).

This characteristic becomes more relevant when the total amount of samples is not enough to be split in training, validation and test datasets, which is common in bioinformatics.

Variable Importance

The aim of each split when a decision tree or a random forest are trained is to decrease the impurity of each subset. The actual amount of impurity reduction can be seen as an index to identify which features are the most relevant in separating the dataset into homogeneous groups with respect to the class label. The impurity decrease is averaged across each tree of the forest during training.

High scores correspond to high impurity reduction, i.e., the corresponding features are more relevant to classification. Usually, these scores are normalized such that the sum of all importance values equals to 1.

Use-Cases

The following are two practical examples of how to use a decision tree or a random forest with real world datasets. They focus on the basics of data analysis in the common software tools R and Python. The full commented source code is available online (see Relevant Websites section), together with the instructions to setup the computational environments.

Predicting Heart Failures with Decision Trees in R

Here, we show how to perform an analysis using a Decision Tree classifier with the R environment. The example dataset is made of 270 patients, where each sample has 13 clinical features (details about the dataset can be found at the dataset webpage (see Relevant Websites section)). The objective of the analysis is to derive a model to detect heart failures, as well as determining which features are the most relevant by examining a small set of decision rules.

First, we load the dataset and split it into a training and a test sets with a 70%/30% ratio

```
data=read.table("heart.txt", header=TRUE, dec=".")
split<-sample(c(1, 2), size =nrow(data),
              replace=TRUE, prob=c(.7, .3))
data.train=data[split==1, ]
data.test=data[split==2, ]
```

Then, we load the R decision tree library and grow an unconstrained decision tree. Specifically, we allow the leaf nodes to contain at least one sample, and internal nodes to have at least two samples in order to be split; furthermore, we choose the Gini Index as splitting criterion. Finally, we don't want to prematurely prune the tree, so we disable this option by setting the parameter `cp` to 0.

```
library(rpart)
settings=rpart.control(minsplit=2,minbucket=1,cp=0)
tree=rpart(num~ .,data=data.train,method="class",
           parms=list(split="gini"),control=settings)
```

We expect the grown tree to be exceedingly large and to overfit the training data, with reduced generalization capabilities on the test set. We evaluate the trained model on both the training and test sets by printing the confusion matrices as well as the total accuracy

```
pred.train=predict(tree, data.train, type="class")
pred.test=predict(tree, data.test, type="class")

#The confusion matrix allows to visualize the type of errors made by the
model
conf.train=table(data.train$num, pred.train)
conf.test=table(data.test$num, pred.test)

#Finally, we evaluate the accuracy
accuracy.train=sum(diag(conf.train))/sum(conf.train)
accuracy.test=sum(diag(conf.test))/sum(conf.test)

cat("Predictions of the grown Classification Tree for the training set:\n")
print(conf.train)
cat(c("Total accuracy: ", round(accuracy.train, 4)*100, "%"))
>Output:
Predictions of the grown Classification Tree for the training set:
absence presence
absence      104         0
presence       0        85
Total accuracy: 100 %

cat("Predictions of the grown Classification Tree for the test set:\n")
print(conf.test)
cat(c("Total accuracy: ", round(accuracy.test, 4) * 100, "%"))
>Output:
Predictions of the grown Classification Tree for the test set:
absence presence
absence       29        17
presence       8        27
Total accuracy: 69.14 %
```

As expected, the performance on the training set is of 100%, whereas the generalization accuracy to samples never seen before is much lower. To reduce the overfitting and improve the generalization capabilities, we will prune the tree, at the expense of a deterioration of the performance on the training set.

```
plotcp(tree)
printcp(tree)
>Output:
      CP nsplit  relerror  xerror   xstd
1  0.4588235     0  1.000000  1.00000  0.080459
2  0.0705882     1  0.541176  0.63529  0.073066
3  0.0470588     3  0.400000  0.51765  0.068353
4  0.0352941     5  0.305882  0.50588  0.067805
5  0.0235294     6  0.270588  0.47059  0.066065
6  0.0176471     7  0.247059  0.43529  0.064176
7  0.0117647     9  0.211765  0.45882  0.065453
8  0.0098039    18  0.105882  0.50588  0.067805
9  0.0058824    25  0.035294  0.52941  0.068887
10 0.0000000    31  0.000000  0.52941  0.068887

#Then we limit the tree at the complexity parameter corresponding to the
#lowest cross-validation error
tree.pruned=prune(tree, cp=0.0176471)
```

The functions `plotcp` and `printcp` show respectively a graph (see Fig. 2) and a table of the cross-validated complexity parameter value (alpha) for each pruned sub-tree. The best pruned tree is selected as the one that achieves the lowest cross-validated error (the y-axis of the graph or the `xerror` column in the table above).

Now we evaluate the classification performance of the pruned tree

```
pred.train=predict(tree.pruned, data.train, type="class")
pred.test=predict(tree.pruned, data.test, type="class")

conf.train=table(data.train$num, pred.train)
conf.test=table(data.test$num, pred.test)

accuracy.train=sum(diag(conf.train))/sum(conf.train)
accuracy.test=sum(diag(conf.test))/sum(conf.test)

cat("Predictions of the pruned Classification Tree for the training
set:\n")
print(conf.train)
cat(c("Total accuracy: ", round(accuracy.train, 4)*100, "%"))
>Output:
Predictions of the pruned Classification Tree for the training set:
      absence presence
absence     96       8
presence    13      72
Total accuracy:  88.89 %

cat("Predictions of the pruned Classification Tree for the test set:\n")
print(conf.test)
cat(c("Total accuracy: ", round(accuracy.test, 4)*100, "%"))
>Output:
Predictions of the pruned Classification Tree for the test set:
      absence presence
absence     35      11
presence     9      26
Total accuracy:  75.31 %
```

By pruning the tree, we obtained two advantages. First, the model is smaller, hence demanding less computational power as well as memory. Second, the generalization capabilities of the model to new subjects have improved. However, we lost some accuracy on the training set.

As a last step, we want to distill the pruned model into a set of intelligible decision rules to gain insights about the most relevant features for the classification

```
#Rule Extraction
library(rattle)
asRules(tree.pruned, compact=TRUE)
>Output:
R 13 [ 6%,1.00] cp=D ca=A oldpeak>=15.5
R  7 [23%,0.95] cp=D ca=B,C,D
R 11 [ 6%,0.83] cp=A,B,C ca=B,C,D slope=2
R 49 [ 2%,0.75] cp=D ca=A oldpeak< 15.5 age< 58.5 age< 41
R 25 [ 5%,0.67] cp=D ca=A oldpeak< 15.5 age>=58.5
R 10 [10%,0.22] cp=A,B,C ca=B,C,D slope=1,3
R 48 [12%,0.13] cp=D ca=A oldpeak< 15.5 age< 58.5 age>=41
R  4 [36%,0.09] cp=A,B,C ca=A
```

For each row, the first number is the index of the corresponding leaf node in the tree. The percentage in the square bracket is the sample coverage of the rule, i.e., the number of samples to which the rule applies, whereas the second number in the square brackets is the probability of the presence of a heart failure.

The obtained decision rules highlight that of the 13 features, only 5 are actually relevant, specifically: the type of chest pain (cp), the number of vessels colored by fluoroscopy (ca), age and two electrocardiography related features (oldpeak and slope).

Predict Relapse of Primary Breast Cancer With Python

In this second example, we show how to build a random forest in Python to discriminate two subtypes of breast cancer. For the purpose, we use a subset of samples from the TCGA Breast Invasive Carcinoma dataset (see Relevant Websites section) already preprocessed as in [Serra et al. \(2015\)](#). The original dataset is heavily unbalanced, here, for the sake of exposition we focus only on the two most common classes, namely Luminal A and Luminal B.

The reduced dataset is made of 114 subjects and for each subject the mRNA expression of 4000 genes are measured by NGS technology. We start by loading the necessary components and the dataset files

```
import numpy as np
import pandas as pd
from sklearn.model_selection import train_test_split, cross_val_score
from sklearn.feature_selection import VarianceThreshold
from sklearn.ensemble import RandomForestClassifier
from sklearn.preprocessing import LabelEncoder
from sklearn.metrics import confusion_matrix

from matplotlib import pyplot as plt

#init PRNG for reproducibility
np.random.seed(123456)

#Load gene expression data
gene_data = pd.read_csv("breast_subtyping.txt", sep='\t')

#Load clinical data
clin_data = pd.read_csv("patient_classes.txt", sep='\t', comment='#')

#Since the dataset is heavily unbalanced, we restrict our example
#to the two most common classes
to_remove = clin_data[(clin_data.x != "LumA") & (clin_data.x != "LumB")].index

Then, we remove any feature which contain NaNs and create the data matrix
and the labels vector.

#Create feature matrix where each row corresponds to a subject
#and each column corresponds to a gene
X = gene_data.T.drop(to_remove).sort_index()
X = X.dropna(axis=1)
print("Input Dataset size is {}".format(X.shape))
#As labels we want learn to predict, we use the status of relapse of each
subject
le = LabelEncoder()
y = le.fit_transform(clin_data.drop(to_remove).x.sort_index())
print("Output label size is {}".format(y.shape))
```

The data is then split into a training and a test sets using the ratio 70%/30%

```
X_train, X_test, y_train, y_test = train_test_split(X, y, train_size=0.7,
stratify=y)
oob_score = True,
n_jobs=1,
)

oob_score = rf.fit(X_train, y_train).oob_score_
oob_scores.append(oob_score)

plt.plot(n_trees, oob_scores, "b")
plt.ylim(.5, 1)
plt.legend(["OOB Accuracy Estimate"])
```

To define the random forest model, we need to define a set of parameters, including the number of trees in the ensemble, the stopping criteria for each tree, the number of features to randomly select and the splitting criterion. These parameters are usually estimated, however, here for the sake of exposition, we will keep them fixed to reasonable values that are known to work well in practice.

We will grow an increasing number of unconstrained trees, like in the previous use case, expecting that overfit trees will produce more independent predictions. Also the size of the random subset of features to be selected is fixed to $\sqrt{p}$, where p is the total number of features, as suggested in Breiman (2001).

However, the number of trees to grow still needs to be estimated. As a rule of thumb, the more trees we grow, the better generalization performance we get until a point where the performance stop to improve. Using more trees than necessary results in a waste of resources.

Fig. 2 Plot of the cross-validated relative error with respect to the complexity parameter. The best model is that corresponding to the lowest cross-validated error.

In the left plot of [Fig. 3](#), we show how the OOB accuracy prediction varies with the number of trained trees. To choose the optimal number of estimators, we inspect the OOB plot to look for the point where the OOB estimate stabilizes. Here, the estimates become more stable after 6001 trees are trained, and therefore we can fix the number of trees to 6001 and compare the OOB performances with the accuracy predictions in the test set.

```
best_rf=RandomForestClassifier(
    n_estimators=6001,
    criterion="entropy",
    min_samples_leaf=1,
    min_samples_split=2,
    max_features="sqrt",
    min_impurity_split=0,
    oob_score=True,
    n_jobs=1,
)
best_rf.fit(X_train,y_train)
print("Test set accuracy of the best model
{:.02f}%".format(best_rf.score(X_test,y_test)*100))
>Output:
Test set accuracy of the best model 80%
```

Finally, we show how to rank the most relevant features with respect to the impurity criterion across all the trees of the ensemble

```
top=10
importances=best_rf.feature_importances_
idx=importances.argsort()[::-1]
pos=np.arange(top)[::-1]+.5
plt.barh(pos,importances[idx[:top]], align="center")
plt.yticks(pos,X.columns[idx[:top]])
```

In the right plot of [Fig. 3](#) we show the 10 most relevant genes in the discrimination of the two subtypes of breast cancer and their relevance value, computed as the average decrease of the impurity criterion across the forest.

Fig. 3 Left: Plot of the out-of-bag accuracy estimate with respect to the number of trees in the forest. Right: The ten most relevant features for the classification of breast cancer subtypes.

Literature Applications

The ease of use, the flexibility and quality of results make Decision Trees and Random Forests two of the most used tools in the field of bioinformatics. Here, we give a few examples from recent literature of applications of the exposed models.

A major field of application is cancer classification, where each observation in the dataset is a subject and the objective is to predict the presence or absence of a cancer disease. Both decision trees and random forests have been applied to the classification of different types of cancer (Chen *et al.*, 2015; Podolsky *et al.*, 2016; Tsai *et al.*, 2016; Venkatesan and Velmurugan, 2015).

The most common features employed are the gene expression levels, measured by microarrays. The number of features that can be simultaneously measured with this technology varies between few hundreds and tens of thousands. Classification in this setting is ill-posed, given that noisy and/or correlated features can harm the final classification performances. To tackle this problem, classifiers are coupled with mechanisms of gene selection, based on variable importance, where the features are ranked based on how much they influence the prediction outcome (Kursa, 2014; Nguyen *et al.*, 2013). A second approach to gene selection is based on meta-heuristic search algorithms like Particle Swarm Optimization among others (Chen *et al.*, 2014), which explores the space of gene subsets searching for the smallest one with the best discriminative power.

Other applications include genome-wide association studies (Botta *et al.*, 2014; Li *et al.*, 2016; Nguyen *et al.*, 2015; Sapin *et al.*, 2015; Stephan *et al.*, 2015) in which genetic variations, usually SNPs, or single nucleotide polymorphisms, correspond to the features and a set of phenotypes of interest are the response variables, like particular traits or diseases. In this case not only it is important to determine a small set of relevant SNPs, but also to highlight which interactions among them trigger the phenotype. Here, the advantage of tree-based models is in the possibility of modeling non-linear interactions without the need to assume a predefined functional form. Furthermore, interactions are taken into account based on statistical or permutation based reasoning or, again, with the use of meta-heuristics like ant colony optimization (Sapin *et al.*, 2015).

Discussion

As every other machine learning model, Decision Trees and Random Forests have their advantages and disadvantages, which make them more or less suitable to tackle a problem. Nonetheless, they have become a major tool in the bioinformatics community, also thanks to a number of software implementations. Decision Trees' strengths are the relatively easy theoretical foundations, the capability to inspect the learned model and the reduced computational requirements. However, the high flexibility of Decision Trees is also a major drawback, since there is a high chance of overfitting.

Random Forests, on the other hand, have almost always better performances at the cost of higher memory requirements and losing model intelligibility, even though it is still possible to evaluate the feature relevance to the classification. Moreover, the lack of a predefined functional form of the interactions between the features and the outcome variable allows both models to automatically tune the complexity of the models on the data at hand.

Conclusions

We introduced the basic concepts of Decision Trees and Random Forests, with particular attention to the bioinformatics community, and we reviewed recent applications of these models while showing basic practical applications. We hope that this short review can be helpful to bioinformatics practitioners.

Basic Concept of Classification and Prediction

Classification is the most common task in machine learning. It works on input data where each item is tagged with a predefined set of categorical labels or classes (Kesavaraj and Sukumaran, 2013). From such training records, the classifier learns a *model* able to distinguish classes or concepts for future predictions of discrete variables.

Using examples labelled with true function values (observation, measurements, etc.), a numerical predictor, or merely a predictor, learns to construct continuous-valued functions as model that predicts unknown or missing numeric values (Han et al., 2012).

Many applications of classification task solve several practical problems, for example, credit risk prediction, based on the knowledge acquired by collecting data from many loan applicants. The output from such a classifier will be one of two possible categorical labels “safe” or “risky”, asserting if a new applicant for a loan is reliable or not.

Similarly, regression models can be used in several fields of interest, for example, in marketing management to predict how much a given customer will spend during a sale. Unlike classification, numeric prediction models continuous-valued function f by mapping the input vector of attributes X to gives ordered continuous values y' as output: $y' = f(X)$.

Model Construction

Building a classifier or a predictor needs a training phase, in which a set of input labelled data, known as the *training set* is shown to the machine. Each item in training set is described by some *features* or *attribute* (qualitative or quantitative) and by a class or a numerical label. In this step, the candidate algorithms learn predetermined data classes or concepts: this is the operation mode of supervised learning. The *validation set* allows selecting the best model among possible candidates, comparing their performances over data never seen before. Finally, when the model was chosen, it needs to assess the machine's ability in classification task on a new data set, so called *test set*. A good classifier or predictor is a machine that inferred the “general” model underlying training data and can apply it to absolve his task on new unseen data.

Role of features

The term *features* holds the meaning of learning, representing the ensemble of characteristics useful to bring out the model from input data. The right model gets the best classification or prediction performances, for this reason, the skill of features extraction is considered a basic part of the classification/prediction task.

Classifier Versus Predictor: Learning, Testing, Accuracy, Overfit

Classification and prediction represent the most used supervised techniques of machine learning (Han et al., 2012). Classifiers and predictors develop their skills starting from training labelled data, discrete or numerical records, and produce categorical labels (classes) or numeric predictions (function values) respectively. The base of operation for both machines is the “model” that must connect the class (discrete or numerical) to the features.

Learning

The first step to constructing a classifier is learning the model from data. The classification model originates from training data, which must be suitably prepared. Data preparation involves (i) cleaning, (ii) relevance analysis and (iii) data transformation:

- (i) In the cleaning step, data are pre-processed to reduce noise and to handle missing values.
- (ii) Relevance analysis consists of correlation analysis and attribute selection: these procedures reduce redundant and irrelevant features, improving classification efficiency and scalability.
- (iii) Then the information contained in training records have to be generalized into concepts, with data dimensionality reduction.

In training phase, the machine is fed with pre-processed data, which is a list of instances, each of them described by some attributes and an assigned qualitative (for a classifier) or numerical (for predictor) label for each. This label represents the “true” class or the function values. Symbolically, the i -th instance is presented to the algorithm by the pair (X_i, y_i) , where $X = (x_1, \dots, x_n)$ is the attribute vector, which is associated to a predefined label y_i . The algorithm increases its knowledge using the information from the training records. The larger is the training set, the better is the classifier/predictor. In particular, a numerical predictor in training phase constructs a function that minimizes the difference between the predicted and true function values.

Model selection depends in comparing different models learned during the training by using validation data set.

Testing and Accuracy

When the training phase finish and the validation procedure selects the best among possible models, a test evaluates the learning degree of the machine. For this purpose, the algorithm will examine a set of data in the same form (X_i, y_i) of the training set. Usually, test sample is achieved randomly selecting 20%–30% of the complete labelled data set.

A comparison between the class or numerical label of each instance in the test set and the corresponding output is used to test the classifier. In particular, the percentage of cases correctly classified in the testing data set gets the accuracy of the classifier, as shown in the formula (1):

$$Accuracy = \frac{p}{t} \quad (1)$$

where p is the number of right classifications and t is the total number of test cases.

For a predictor the accuracy is provided by measuring the “distance” between the actual value y_i and the predicted value y'_i corresponding to each vector of input attribute X_i . *Loss functions* provide these kind of error measures. The following expressions (2,3) shows the most common loss functions:

$$Absolute\ error: |y_i - y'_i| \quad (2)$$

$$Squared\ error: (y_i - y'_i)^2 \quad (3)$$

Starting from these expression, the average loss over the test set is obtained by the error rates in expressions (4) and (5):

$$Mean\ absolute\ error: \frac{\sum_{i=1}^d |y_i - y'_i|}{d} \quad (4)$$

$$Mean\ squared\ error: \frac{\sum_{i=1}^d (y_i - y'_i)^2}{d} \quad (5)$$

where d is the total number of test instances.

Evaluation of classification and prediction methods can also consider other criteria like:

- speed: time to construct the model; time to use the model;
- robustness: noise and missing values;
- scalability: efficiency in disk-resident databases;
- interpretability: understanding and insight provided by the model.

Generalization and Overfitting

The construction of classification model is based on a suitable choice of features, in type and number. Performances of the classifier can be enhanced by raising the number of features and producing sophisticated *decision boundary* among data. This choice can lead to excellent performances on the test set but can result in poor performances on new patterns. This declining performance is a symptom of the problem of *overfitting*. It means that a complicated model with a complex decision boundary can give poor *generalization* capability.

To avoid this effect, it is desirable looking for a general model. Indeed, the robustness of the algorithm depends on the degree of generalization, namely the capacity of working with the crucial features of data and choosing general rules for the model.

Further Considerations

The simpler classification problem is the binary classification. The binary or two-class classification has several applications, for example, in problems regarding credit/loan approval or medical diagnosis. Moreover, classification techniques provides solution also for problems involving more than two classes, dealing with *multi-class classification* (see also the section about multi-class classification in SVM section) (Li et al., 2004; Zhou et al., 2017).

It is possible to forecast numeric values with regression. Three types of regression analysis can be conduct:

- (i) Linear and multiple regression.
- (ii) Non-linear regression.
- (iii) Other methods, such as generalized linear model (GLM), Poisson regression, regression trees.

A discussion of such methods will be subject to the following paragraphs and the next article.

Classification by Decision Tree Induction: ID3 (Iterative Dichotomiser), C4.5, CART (Classifier and Regression Trees)

In a classification task, the objects of the universe are described by a set of attributes and their values. To distinguish an object from others, the classifier has to absolve the *induction task* (Quinlan, 1986). The induction task consists in developing a classification rule able to identify the class of any object of the universe from the value of its attributes that represents some important characteristics or *features* of object.

A decision tree classifier is a simple and widely used classification technique. As other classification methods, it builds a classification model learning from a bunch of input data. By analogy with a botanical tree, the structure of the decision tree consists of a flowchart with a root, branches, internal nodes and leaves. Each structural element of a tree identifies a step in a splitting data process, whereby the tree algorithm separates input training items by testing their different characteristics, i.e., different values of *some* their attributes.

In particular, the classification process of an object starts from the *root* that is the feature always tested for each instance. The different values of root attribute lead to different possible paths on the tree, addressing the algorithm to a specific *branch*. The decision process continues in the next *internal node*, where a new attribute test run over another instance attribute until the reaching of a *leaf node*, representing the class that owns the instance considered.

Decision tree classifiers are employed extensively in several fields of interest, such as medical diagnosis, weather prediction, fraud detection, credit approval, target marketing, customer segmentation (Lavanya and Rani, 2011). Their hallmarks are: (i) providing intelligible classification rules, (ii) ease to interpret, (iii) speed of construction, (iv) high accuracy. Often expert systems use decision tree, because they offer results comparable to expert human skills.

Build a Tree: Divide-and-Conquer Algorithm

The build or growth phase of tree begins from the choice of the root. Numerical computations based on information theory (see Sections Information gain and Gini index) establish which attribute ought to be the root, or an internal node. Its values will be the branches that separate the training data in subsets (attribute test). In the next step, for each branched subset the algorithm iterates the numerical computation on remaining attributes in order to find the following node and further divides data. Tree expansion process stops when a leaf node arrives, namely when each item of the analyzed subset gives the same overcome of the attribute test: this value represents the *class label* (Lavanya and Rani, 2011). In this ideal case, leaf node is *pure*, including elements with the same category label. However, usually such a leaf node is not obvious, because it can contain a mixture of elements with different label class. In this more recurrently case, the algorithm uses a different stopping criterion, accepting such as imperfect decision in favor of a simpler, more generic tree structure. As an example, in Fig. 1 is shown a training set and the related tree, proposed by Quinlan (1986). Here, the classifier suggests if “Saturday morning” is suitable or not for some activity, respectively with the leaf node Yes or No, starting from its weather attributes.

Fig. 1 Example of training set and related tree. The example is referred to the question if “Saturday morning” is suitable or not for some activity. Reproduced from Quinlan, J.R., 1986. Induction of decision trees. Machine Learning 1, 81–106.

An adequate choice of features allows build a decision tree that provides a correct classification for each object in the training data set. Nevertheless, the scope of induction task is implementing a classifier able to label correctly other unseen objects as well. Therefore, the decision tree must catch the underlying connection between an object's class and values of its attributes.

It is possible to build more than one tree starting from a training set; in general, it is better to choose the simplest tree in order to avoid overfitting problems and guarantee a proper classification of new objects. Indeed, it would be expected that the simpler tree works better than others tree trained on the same data set, because it more likely that correctly classifies more objects unseen (Quinlan, 1986). For this reason, in the most of cases, the algorithm uses a nontrivial stopping criterion in growing procedure, considering a mixture of elements with different label class as a leaf node and accepting such as imperfect decision in favor of a simpler, more generic tree structure. Furthermore, *pruning* operation generalizes the tree structure where branches are redundant, therefore removing noise and outliers.

The frequently used decision tree algorithm are Iterative Dichotomiser 3 (ID3), C4.5 and CART.

ID3

ID3 is a decision tree algorithm with an iterative structure based on Hunt's Concept Learning Systems (Hunt, 1962; Hunt et al., 1966). During the learning process, only a subset of training data is selected randomly to form a first decision tree. If this tree correctly classifies also all the other objects in the training set, then it represents the correct tree and the research process finish. Otherwise, a new subset or *window* of training records is chosen to form a new tree, including a selection of the incorrectly classified objects. This iterative process continues until the decision algorithm is able to classify correctly the entire training data set. The main advantage of ID3 strategy allows identifying the correct decision tree with few iterations even on training set containing thousands of items.

C4.5 algorithm

An improvement of ID3 is C4.5 algorithm, also developed by J. Ross Quinlan in 1993. C4.5 works with multiway splits in attribute test (Chen et al., 2015). C4.5 introduces some advantages with respect to ID3, working with both categorical and numerical (or continuous) attributes, and handling missing attribute values. Moreover, it employs information-based criteria as attribute selection measure. Furthermore, it uses pruning phase when the tree building is completed. Pruning allows handling the overfitting problem, wherein the decision tree algorithm may incur.

Classification and regression tree

Classifier and regression trees (CART) is a decision tree technique (Breiman et al., 1984) can perform both tasks of classification and regression, depending on the input data nature, categorical or numerical respectively. In particular, leaves of regression tree predict real numbers (Rokach and Maimon, 2005).

CART splits data by binary attribute tests, driven by pre-set criteria that establish when the growing process stops (Wu et al., 2008). The tree represents a series of rules opportunely fixed, learned by training data set, in order to predict a likely class label for a new examined case (Lawrence and Wright, 2001). Pruning is used to address the overfitting problem, which is recurrent also for CART.

Attribute Selection Measures

Information Gain and Gini Index are two split criteria widely used in the decision tree literature. Split criteria perform attribute selection for each node, when growing the tree.

Choosing correctly attributes is extremely important for proper classification, since from this depends the data split and the consequent performance of the tree. It is not obvious to determine which criterion is the best for a given data set (Raileanu and Stoffel, 2004).

Information gain

The decision tree algorithm uses a set of measures of entropy or impurities to evaluate the best choice for the node attribute. Indeed, a good attribute splits the data by grouping the greatest number of cases that belong to the same class, so that a successor node is as pure as possible. For this reason, it is indicative a measure of "order", defined as the number of items belonging to the same class; obviously, the more items belong to the same class, greater will be the order degree. Entropy is a measure of disorder, and represents the amount of information. Entropy is null for a pure node (leaf) and becomes maximum when all the classes at node N are equally likely. Therefore, given a set S of examples and n classes, the *entropy* is expressed by Eq. (6)

$$E(S) = \sum_{i=1}^n -p_i \log_2 p_i \quad (6)$$

where p_i is the portion of examples in i -th class (entropy of set S is constant for all attribute).

To compute the quality of the split on an entire attribute A, the weighted average is calculated over all sets resulting from the split on all values of A: $I(S,A)$ is the *average entropy for attribute A* and is defined as in Eq. (7):

$$I(S,A) = \sum_j \frac{|S_j|}{S} E(S_j) \quad (7)$$

where S_j represents the j -th subset of S depending on the j -th value of the attribute A . The *information gain* for attribute A is the information gained by branching on A is shown in Eq. (8):

$$\text{Gain}(S, A) = E(S) - I(S, A) \quad (8)$$

A good rule to tree growing consists of choosing that attribute for which the gain of information is maximum, or equivalently, that attribute with minimum average entropy (Han et al., 2012).

Information gain is used as attribute selection measure in ID3 e C4.5 algorithms.

Gini index

Gini Index is an inequality measure, employed in several scientific fields. In decision tree learning, Gini index is another method to assess purity/impurity of a node. Mathematical expression of Gini impurity of a set S_m of records at a given node m is the following Eq. (9):

$$i(S_m) = \text{Gini}(S_m) = 1 - \sum_{j=1}^n p_j^2 \quad (9)$$

where p_j is the portion of records belonging to j -th class, over a total of n classes. For Gini index, each attribute determines a binary data split. Gini index measures impurities of each possible pairs of partitions S_{m1} and S_{m2} for a given attribute A , as shown in formula (10):

$$\text{Gini}_A(S_m) = \frac{S_{m1}}{S_m} \text{Gini}(S_{m1}) + \frac{S_{m2}}{S_m} \text{Gini}(S_{m2}) \quad (10)$$

The attribute with the partition having minimum Gini index is chosen to continue the tree building process (Han et al., 2012). Gini index is usable in problem with two or more categories and is employed as attribute selection measure in CART algorithm.

Rule-Based Classification

Rule models are the second major techniques used in machine learning after the decision tree methods. Trees offer a first, although rigid example of rules as seen in branching process, since each branch dictates univocal way to browse the tree. Instead, in a rule model the algorithm may infer further information from the possible overlapping among several rules. As well as the decision trees, the Rule-Based Classifiers are highly expressive, easy to generate and to interpret. Their performances are comparable to decision trees. Moreover, rules methods can classify rapidly new instances and can easily handle missing values and numeric attributes (Tan et al., 2005). Rule-based methods form an integral part of expert systems in artificial intelligence.

If-Then Rules

A rule-based classifier uses a collection of rules of the type, "If.... Then..." to absolve the classification task. The expression following "If" states a condition or predicate (antecedent rule or left-hand side, LHS) that is a conjunction of attributes value. The class is defined after the keyword "then", which is the consequent (or right-hand side, RHS) of the rule. In a data set of records to classify, an instance is labelled according to the conditions verified by his attributes. The label class will be assigned to the instance whose attributes verify the condition of a rule r ; in this case, the rule r covers the considered instance. If attributes of the instance do not satisfy any rule, the item label will be that of a default class (Wu et al., 2008).

Building Classification Rules

A method to build a rule-based classifier is to extract rules directly from the data (Kesavaraj and Sukumaran, 2013), as done by PRISM (Cendrowska, 1987), RIPPER (Cohen, 1995), 1R (Holte, 1993) and CN2 (Clark and Niblett, 1989), which employ the so-called Direct Method, that will be explained below. Alternatively, it is possible to construct a rule classifier using an Indirect Method, which extract rules from other classification models, for example, decision trees. The algorithm learns first the tree structure and then converts it in rules. C4.5rules or PART are examples of rule-based classifier build using indirect method.

Direct method: Sequential covering

Sequential covering method aims to create rules that describe or cover many examples of a class and none or very few of other classes. Covering algorithm, descending from *covering strategy* (Michalski, 1969, 1975; Fürnkranz and Flach, 2005), is the typical rule learning method. It consists in iteratively learning one rule from training set and subsequently removing the example covered by that rule from the training set (Fürnkranz, 1999, 2010) (see Fig. 2). The training set is therefore *separate*, and recursively the algorithm learns another rule that covers some of the remaining examples *to conquer* (cf. separate-and-conquer method, Pagallo and Haussler (1990)). In particular, to learn a rule for a class, the algorithm starts from an empty rule, which is unable to discern among the entire input data set. Then, this rule is enriched by adding new attribute test that can describe a fraction of example in training set. As for the decision tree, the rule algorithm selects an attribute used to split data according to the amount of

Fig. 2 Successive iterations of coverage learning: fraction of positive examples (squares), covered by a rule, discarded from original data set.

Fig. 3 Enrichment of a rule by adding a new combination of attribute test leads to a reduction of covered examples (left panel) and allows to improve the classification (right panel).

information contained in it by means of some test selection criteria such as accuracy or information gain (for accuracy, see below; for information gain, see the previous section). By adding more conditions to the rule, its coverage is reduced (see Fig. 3). The growing rule continues until training set cannot be split any further or another stopping criterion is met. The pseudo-code for sequential covering algorithm is shown in Fig. 4.

Evaluation of a rule and stopping criterion

Quality of a classification rule can be evaluated by Coverage and Accuracy. *Coverage* of a rule r represents the fraction of instances that satisfy the antecedent of a rule, as expressed by the Eq. (11):

$$\text{Coverage}(r) = \frac{|LHS|}{n} \quad (11)$$

where n is the total number of records in sample considered. An equivalent form for coverage is $C=t/n$, where $t=|LHS|$ is the total number of records covered by rules.

Accuracy of a rule r is the fraction of records covered by the rule that belong to the correct class, in RHS of rule, as shown in Eq. (12):

$$\text{Accuracy}(r) = \frac{|LHS \cap RHS|}{|LHS|} \quad (12)$$

Sequential Covering Algorithm

1. LearnedRules = { }
2. Rule = Learn1Rule (class, Attributes, Threshold)
3. While (Performance (Rule, Examples) > Threshold)
4. LearnedRules = LearnedRules + Rule
5. Examples = Example – Covered (Examples, Rule)
6. Rule = Learn1Rule(class, Attributes, Examples)
7. Sort (LearnedRules, Performance)
8. Return LearnedRules

Fig. 4 Pseudo-code for the sequential covering algorithm.

Rules accuracy can be expressed in the more compact form $A=p/t$, where p are positive examples, i.e., records with class correctly predicted by rule and t is the total number of records covered by rule. It is immediate to consider the difference $t - p$ as the number of errors made by rule. Other metrics of rules evaluation are illustrated in [Fürnkranz \(1999\)](#).

Often, accuracy of a rule is adopted as stopping criterion of rule construction. In particular, the building process stops when accuracy of the rule is maximal, or when increasing in accuracy gets below a given threshold.

When the rule classifier is constructed, *test set* allows evaluate model accuracy.

Conflict resolution and overlap problem

It can occur that one instance triggers more than one rules. In this case, conflict resolution is operated by three possible strategies:

- Size ordering: rules with wider LHS condition have the highest priority.
- Class-based ordering: rules belonging to the same class are grouped together and classes appear by decreasing of prevalence, being class prevalence the fraction of instances that belong to a particular class.
- Rule-based ordering (decision list): rule sets are ordered by priority list, depending on measures of rule quality or experts knowledge.

Some rules can become over specialized, incurring in the overfitting problem. A solution for this inconvenience is to prune the rules, by using *validation set*. Two main strategies are *incremental pruning* and *global pruning* ([Tan et al., 2005](#)).

Classification by Multilayer Feed-Forward Neural Networks (Backpropagation, Sigmoid Function, Learning Rate)

Conventional machine learning techniques require considerable domain expertise and engineering skills to extract right features from raw data and so to detect pattern or classify the input. Artificial Neural Networks (ANN) or also Neural Network (NN) allows solving problems where features detection is difficult. They are used in domains like biomedical field ([Dreiseitl and Ohno-Machado, 2002](#)), computer vision and speech and image recognition, drug discovery and genomics ([LeCun et al., 2015](#)).

Neural Networks are computational methods whose structure follows the information processing model of the biological brain ([McCulloch and Pitts, 1943](#); [Widrow and Hoff, 1960](#); [Rosenblatt, 1962](#); [Rumelhart et al., 1986](#)). Feedforward neural networks architecture is the first and simplest kind of neural network. It represents a powerful tool for handle non-linear classification (see note in the following section) and regression problems.

Difference Between Linear and Non-Linear Classifier

It can be helpful to visualize a geometric description of the classification problem, by plotting the data in a so-called *feature space*. The feature space is a mathematical formalization used to represent the data based on a characterizing collection of data features. The axis in a such space correspond to the features chosen for describe each instance in the data set. A two-class linear classifier discerns between possible cases using a linear combination of the features and a numerical threshold ([Fig. 5](#)). An item will belong to a particular class rather than to the other one if the weighted sum of its features is above or below a given threshold.

Neural network methods take advantage from composing simple non-linear computational modules that deform the input data space to make classes of data separable by a linear decision boundary.

Fig. 5 Two-class linear classification, plotted in a 2-dimensional feature space. The red straight line is the decision boundary among positive and negative examples. $w=(w_1, w_2)$ is the vector of weights and $x=(x_1, x_2)$ is the vector of features on which to perform the classification for a given instance.

Fig. 6 Schematization of a single neuron.

NN: Perceptron, Multi-Layer Perceptron and Feedforward Neural Network Architecture

Neural network algorithms are used for both supervised and unsupervised learning. To absolve the classification task, supervised neural networks is trained with inputs data and their respective targets or classes.

Neural networks have a peculiar architecture inspired by the biological functioning of neurons. In this analogy, a single neuron, also called perceptron, works as a classifier: for each item to classify, it receives several feature inputs x_i with a corresponding weight w_i and produces an output y (see Fig. 6). The output value of a neuron is called activation a and it is a function of the sum of the weighted inputs: $a = \sum_i w_i x_i$, where the sum run over the total number n of features. There are several types of output or activation function $y=f(a)$, Table 1 shows some types of activation function.

A neural network is a connection of many neurons. In the example of Fig. 7, the outputs of a single neuron in a layer feed each neuron in the successive layer, in the “fully connected” model. The “depth” of the network depends on the number of hidden layers, rising from a simple model of two layer, where only a layer is hidden, until to a multilayer network.

The most simple grouping is *single layer perceptron* (SLP), consisting of an input and an output layer (Jain et al., 1996). *Multilayer perceptron* (MLP) represents an advanced version of the standard SLP, where more layers of computing units connected to each other make a wider network. Unlike SLP, the MLP can discern data non-linearly separable by employing sigmoid non-linear activation function as shown in Fig. 8. The continuity property of sigmoid function will be central in network training.

Feedforward neural network (FNN) is a multilayer perceptron where, as occurs in the single neuron, the decision flow is unidirectional, advancing from the input to the output in successive layers, without cycles or loops. This aspect makes FNN the simplest example of neural network.

Training the network

In training phase, a feedforward network examines examples that show the relationship between a feature vector x as input and a target t . The number of times the entire training set is fed to the network is known as *epoch*. From this training data, the network should learn the correct model of classification according to which a given input x correspond to an output y close enough to the right answer t . The ‘distance’ between the target t and the output $y(a)=y(x,w)$ is evaluated for each pair (x,t) by the *objective function*

Table 1 Synoptic table of deterministic activation functions

Activation function	Analytical expression	Graphic representation
Linear	$y(a) = a$	
Sigmoid logistic	$y(a) = \frac{1}{1+e^{-a}};$ $y \in (0,1)$	
Sigmoid tanh	$y(a) = \tanh(a);$ $y \in (-1,1)$	
Step	$y(a) = \begin{cases} 1 & \text{if } a > 0 \\ -1 & \text{if } a \leq 0 \end{cases}$	

**Fig. 7** Example of a two layer, fully connected network (do not count the input layer).

or error function $E = E(y, t)$, which reports how well the network solves the task. The training process consists in a minimization of objective function, by varying the weight parameters w . For function minimization is evaluated also the gradient of the objective function with respect to w by using the *backpropagation algorithm*.

Backpropagation and learning rate

The backpropagation algorithm applies chain rule for derivatives to the objective function $E(y, t)$ with respect to the weights w , relying on gradient descent. Thus $E(y, t)$ and consequently $y(x, w)$ must guarantee both continuity and differentiability. For

Fig. 8 Multilayer neural network schematized by fully connected black dots: from left to right – two input unit, two units in the hidden layer and one output unit. The hidden layer deforms the input space to obtain a linear decision boundary between classes of data, as highlighted from the shape of the border between colored areas. Reproduced from LeCun, Y., Bengio, Y., Hinton, G., 2015. Deep learning. *Nature* 521, 436–444.

backpropagation networks, Sigmoid activation function is preferred to step function used in perceptron; the objective function of the network is often defined as (using least squares methods as optimization technique. An alternative to optimization function is cross-entropy (with the relative maximum likelihood estimation method). $E = \frac{1}{2} \sum_{i=1}^p (y_i - t_i)^2$, for a training set containing p records. The learning rule for neural network relies on gradient descent procedure that allows minimizing E starting from its gradient $\nabla E = \left(\frac{\partial E}{\partial w_1}, \frac{\partial E}{\partial w_2}, \dots, \frac{\partial E}{\partial w_l} \right)$ with respect to l weights. The weights, initialized with random values, represents the only tuning factor to minimize the error function through a change $\Delta w_i = -\eta \frac{\partial E}{\partial w_i}$, where η is the *learning rate* (Royas, 1996). This latter can be a constant value or can be a decreasing function of simulation time τ such as η_0/τ , where τ is an integer counting the algorithm steps. Learning rate denotes the amount of the weights' variation or the length of the step of each iteration in the negative gradient descent.

Support Vector Machines

Support vector machine (SVM) is a supervised machine learning technique based on statistical learning theory (Vapnik, 1995; Scholkopf et al., 1995; Cristianini and Shawe-Taylor, 2000). SVM is a binary classifier (the term “machines” descends from the fact that SVM algorithm produces a binary output), but it can handle problems with many classes and also numerical prediction tasks (Wang and Xue, 2014; Wu et al., 2008). Furthermore, it can treat non-linearly separable data. Similarly to neural network, SVM employ a non-linear mapping of input vectors in a high-dimensional features space, where it can linearly separate data, by so-called optimal separating hyperplanes (Chen et al., 2015).

SVM algorithms allow approach many problems of different domains, such as pattern recognition, medical diagnosis, marketing (Yingxin and Xiaogang, 2005) or text classification (Minsky, 1961; Joachims, 1998).

Linearly Separable Data

Support vector machines mainly works as binary classifier, separating data in a linear way. Data are linearly separable when it is possible to split them in two groups by using a straight line in a two-dimensional input feature space (the feature space is a mathematical formalization used to represent the data based on a characterizing collection of data features) or a plane in a 3D feature space. More generally, for an N -dimensional space the *hyperplane* $N-1$ -dimensional divides data and it represents the decision boundary. There are several ways to separate linearly the same data set, as shown in Fig. 9.

SVM algorithm searches for the optimal separating hyperplane, considering the notion of *margin* m , defined as the distance between the separating hyperplane and the nearest training examples, at least one for each class. In particular, the points closest to the decision boundary, known as *support vectors*, should be far away from it as possible. Indeed, maximizing the margin in training phase makes the classifier more robust and gives better classification performance on test data. In general, training a SVM aims at finding the proper decision boundary or separating hyperplane with the largest margin. Support vectors identify the *optimal* decision boundary and determine the margin, evaluated as the distance between them (Cristianini and Shawe-Taylor, 2000).

As shown in Fig. 10, the margin has an amplitude equal to $m/\|w\|$, measured on w (vector of weights). Therefore, maximizing the margin corresponds to minimizing $\|w\|$, which results in solving a constrained optimization problem, considering a quadratic function such as that shown in formula (13):

$$w^*, t^* = \arg \min_{w,t} \frac{1}{2} \|w\|^2 \text{ subject to the constraint } y_i(w \cdot x_i - t) \geq 1 \quad (13)$$

where $1 \leq i \leq n$ and n is the number of training examples.

Fig. 9 Linearly separable data (A); different possibilities to separate data are shown in (B)–(D) panels.

Fig. 10 Geometry of a SVM classifier. Dashed lines delimit the margin. The support vectors are training examples circled and nearest to decision boundary t .

The constraint expresses the request that instances remain outside the margin. In **Fig. 10**, the hyperplanes of equation $w \cdot x_i - t = \pm m$ delimit the margin of separation between two classes y_i of data, positives and negatives respectively. In particular, positives must verify the condition $(w \cdot x_i - t) \geq 1$ and negatives $(w \cdot x_i - t) \leq -1$, where m is set to 1, as usual (the parameters t , $\|w\|$ and m can be rescaled for convenience). The product between classes $y_i = \pm 1$ (assigned in binary supervised problems) and the previous conditions allows formulate a compact constraint (Eq. 13), valid for all instances.

The Lagrange multipliers method approaches the optimization problem applied to the function to minimize under the condition shown by Eq. (13). The Lagrange multipliers algebra allows to obtain the optimal value for the weight ($w = \sum_{i=1}^n \alpha_i y_i x_i$, where α_i are the Lagrange multipliers and n is the number of training examples) w and for the decision boundary t , starting from the pairs (x_i, y_i) , which are provided as input in training phase of SVM. Laid out these values, SVM will establish the class of a new instance according to the following formula (14):

$$y' = \text{sgn}[w \cdot x' - t] \quad (14)$$

The Lagrange function incorporates the constraint preceded by the Lagrange multipliers α_i , as shown in the Eq. (15) (according to the “hinge” loss function formulation (Hastie et al., 2008):

$$\begin{aligned}
\Lambda(\mathbf{w}, t, \alpha_1, \dots, \alpha_n) &= \frac{1}{2} \|\mathbf{w}\|^2 - \sum_{i=1}^n \alpha_i (y_i (\mathbf{w} \cdot \mathbf{x}_i - t) - 1) \\
&= \frac{1}{2} \|\mathbf{w}\|^2 - \mathbf{w} \cdot \left(\sum_{i=1}^n \alpha_i y_i \mathbf{x}_i \right) + t \left(\sum_{i=1}^n \alpha_i y_i \right) + \sum_{i=1}^n \alpha_i
\end{aligned} \tag{15}$$

By setting to zero the partial derivative of the Lagrange function with respect to t and $\mathbf{w}$, it is possible obtain the following values:

$$\frac{\partial}{\partial \mathbf{w}} \Lambda(\mathbf{w}, t, \alpha_1, \dots, \alpha_n) = 0 \rightarrow \mathbf{w} = \sum_{i=1}^n \alpha_i y_i \mathbf{x}_i \tag{16}$$

$$\frac{\partial}{\partial t} \Lambda(\mathbf{w}, t, \alpha_1, \dots, \alpha_n) = 0 \rightarrow \sum_{i=1}^n \alpha_i y_i = 0 \tag{17}$$

Returning these values into the Lagrange function (15), the primal problem changes in the dual optimization problem expressed in Eq. (18), entirely depending from the Lagrange multipliers:

$$\begin{aligned}
\Lambda(\alpha_1, \dots, \alpha_n) &= -\frac{1}{2} \left(\sum_{i=1}^n \alpha_i y_i \mathbf{x}_i \right) \cdot \left(\sum_{i=1}^n \alpha_i y_i \mathbf{x}_i \right) + \sum_{i=1}^n \alpha_i \\
&= -\frac{1}{2} \sum_{i=1}^n \sum_{j=1}^n \alpha_i \alpha_j y_i y_j \mathbf{x}_i \cdot \mathbf{x}_j + \sum_{i=1}^n \alpha_i
\end{aligned} \tag{18}$$

To solve the dual problem it is necessary maximize (the dual Lagrange function (19) is maximized being the α_i preceded by a minus sign in Eq. (15)) the function $\Lambda(\alpha_1, \dots, \alpha_n)$ as described in the following expression:

$$\begin{aligned}
\alpha_1^*, \dots, \alpha_n^* &= \arg \max_{\alpha_1, \dots, \alpha_n} = -\frac{1}{2} \sum_{i=1}^n \sum_{j=1}^n \alpha_i \alpha_j y_i y_j \mathbf{x}_i \cdot \mathbf{x}_j + \sum_{i=1}^n \alpha_i \\
\text{subject to } \alpha_i &\geq 0, \quad 1 \leq i \leq n, \quad \sum_{i=1}^n \alpha_i y_i = 0
\end{aligned} \tag{19}$$

As shown in the Eq. (19), the optimization problem consists in pairwise dot products between training instances, which is expressed by the element of the Gram matrix $H_{ij} = \mathbf{x}_i \cdot \mathbf{x}_j$.

The condition $\alpha_i \geq 0$ is typical for support vector machines (the constraint in Eq. (15) being non-negative) and include two possible cases: (i) $\alpha_i = 0$ for an example $\mathbf{x}_i$ that does not contribute to learn the decision boundary; (ii) $\alpha_i > 0$ only for support vectors, namely, for examples, nearest to the decision boundary. The Lagrange multipliers non-zero determine the decision boundary through the expression (16) and (17) and consequently the class of each new instance through the Eq. (14).

Linearly Inseparable Data

Soft margin

SVM can be adapted to non-linearly separable cases (Cortes and Vapnik, 1995) introducing *margin errors* ξ_i , which allow to some of the training examples to be inside the margin or even at the wrong side of the decision boundary Fig. 11. The *slack variables* ξ_i leads to a *soft margin* optimization problem:

$$w^*, t^*, \xi_i^* = \arg \min_{w, t, \xi_i} \frac{1}{2} \|\mathbf{w}\|^2 + C \sum_{i=1}^n \xi_i \text{ with the constraint } y_i (\mathbf{w} \cdot \mathbf{x}_i - t) \geq 1 - \xi_i \tag{20}$$

where $\xi_i \geq 0$ and $1 \leq i \leq n$.

C is a "cost" parameter that controls the tradeoff between margin maximization against slack variable minimization. Based on the penalization method, C represents the "modulator" of the slack variables, which work as penalty term for deviations on the wrong side of the margin.

In soft margin case, the Lagrange function becomes the Eq. (21):

$$\begin{aligned}
\Lambda(\mathbf{w}, t, \xi_i, \alpha_1, \dots, \alpha_n, \beta_i) &= \frac{1}{2} \|\mathbf{w}\|^2 + C \sum_{i=1}^n \xi_i - \sum_{i=1}^n \alpha_i (y_i (\mathbf{w} \cdot \mathbf{x}_i - t) - (1 - \xi_i)) - \sum_{i=1}^n \beta_i \xi_i \\
&= \frac{1}{2} \|\mathbf{w}\|^2 - \mathbf{w} \cdot \left(\sum_{i=1}^n \alpha_i y_i \mathbf{x}_i \right) + t \left(\sum_{i=1}^n \alpha_i y_i \right)
\end{aligned}$$

Fig. 11 Non-linear separable case: the distance between the red or blue example into the margin is $-\xi_i / \|w\|$.

$$\begin{aligned}
 & + \sum_{i=1}^n \alpha_i + \sum_{i=1}^n (C - \alpha_i - \beta_i) \xi_i \\
 & = \Lambda(w, t, \alpha_i) + \sum_{i=1}^n (C - \alpha_i - \beta_i) \xi_i.
 \end{aligned} \tag{21}$$

For an optimal solution every partial derivative with respect to ξ_i should be zero, and consequently for all i follows the Eq. (22):

$$C - \alpha_i - \beta_i = 0 \tag{22}$$

Therefore, vanishing the adding term in the last expression of Eq. (21), the non-linear dual problem is reduced to the linear one in formulation (19) with the addition of the upper bound on α_i derived from β_i (22): $0 \leq \alpha_i \leq C$.

With regard to the meaning of the upper bound of α_i , the equality to C implies that $\beta_i = 0$, concerning the case in which training examples are on or inside the margin, being respectively $\xi_i = 0$ or $\xi_i > 0$.

Kernel trick

Non linearly separable data can be treated plotting them in a higher dimensional feature space through a mathematical transformation known as *kernel function* k . Such function replaces the inner products between pairs of input instances $x_i \cdot x_j$ in the SVM algorithm for linear separable data, and allows to represent training examples without the explicit computation of their coordinates in the new feature space. The formulas (23) and (24) express that in symbol:

$$k : x \rightarrow \Phi(x) \tag{23}$$

and

$$H_{ij} = \Phi(x_i) \cdot \Phi(x_j) = k(x_i, x_j) \tag{24}$$

where $\Phi(x)$ is the feature mapping of the instance x in the new feature space, performed by the kernel function k and $k(x_i, x_j) = \Phi(x_i) \cdot \Phi(x_j)$ is the Kernel matrix element, which provides the Gram matrix element H_{ij} already seen above transformed by k . Popular kernels are listed in Table 2.

With kernel function, the mapping in a higher dimensional space can make possible separate linearly data that in the starting feature space are non-linearly separable, as shown in Fig. 12.

Finally, for each new instance x' the class is established through the expression:

$$y' = \text{sgn}[w \cdot \Phi(x') - t] \tag{25}$$

where $w \cdot \Phi(x') = \sum_{i=1}^n \alpha_i y_i \Phi(x_i) \cdot \Phi(x') = \sum_{i=1}^n \alpha_i y_i k(x_i, x')$.

This means that classifying a new instances involves training examples with non-zero Lagrange multipliers.

Multiclass SVM

It is possible to use additional methods that extend the SVM classification to more than two classes. (Weston and Watkins, 1999; Crammer and Singer, 2001; Hsu and Lin, 2002; Wang and Xue, 2014). Among the strategies aimed to adapt SVM to multiclass classification, there are two common techniques: *one-versus-all* (Vapnik, 1998) and *one-versus-one* (Kreßel, 1999). Both approaches decompose the single multiclass problem into a set of binary classification problems. To solve a problem with k classes, the one-versus-all approach trains k SVM binary classifiers so that i -th model recognizes as positives the examples in the i -th class and as

Table 2 a, b, γ are parameters defining the behavior of kernel function

Kernel function	Analytical expression
Linear	$k_0(x_i, x_j) = x_i \cdot x_j$
Polynomial	$k_1(x_i, x_j) = (x_i \cdot x_j + a)^b$
Gaussian	$k_2(x_i, x_j) = \exp\left(-\frac{\ x_i - x_j\ ^2}{2\gamma^2}\right)$
Sigmoidal	$k_4(x_i, x_j) = \tanh(a(x_i \cdot x_j) - b)$

**Fig. 12** Left: in the starting 2D feature space data are not linearly separable; right: kernel trick allows to map data in a 3D new feature space, where data are linearly separable by means of a hyperplane.

negatives all the rest of examples. In the test phase for a given input, the binary classifier that provides positive output value assigns the class label.

The one-versus-one (Kreßel, 1999) method solves the k classes problem with a pairwise decomposition of classifiers. This approach uses $k(k-1)/2$ binary classifiers, each one of them is trained to identify as positive a given class and negative all the rest (in a similar way as described above). In the test phase, a given input instance is evaluated or “voted” from pairs of classifiers. The class label of this test instance will arise from the classifier that gives the highest number of votes.

Associative Classification: Classification Based on Association Rules

The rules syntax concerns different machine learning areas. As shown above (see Section Rule-Based Classification), supervised learning employs rules to absolve some classification tasks. But rules paradigm also take place in the unsupervised learning, with the association rules (Cios et al., 2007). Both approaches have a large use for many application domains (Gosain and Bhugra, 2013), according to their proper characteristics and differences.

Introduction of Association Rules

Association rules (AR) (Agrawal et al., 1993) represent a technique of unsupervised learning focused on the identification of relationship of co-occurrence, named associations, among items in a data set. The original application of this kind of rules is market basket data analysis, aimed at discovering possible regularities of association among items on sale and therefore to support market decision making. AR are relevant for cross-marketing. However, many other applications range in different contexts, from Web and text document (Kulkarni and Kulkarni, 2016) to Bioinformatics domain (Atluri et al., 2009).

Rule-Based Classification section is based on a “small set” of rules mined from a database in order to achieve as accurate as possible result. The objective of AR mining is finding in the database “all” rules that satisfy a given minimum support and minimum confidence threshold (Agrawal and Srikant, 1994). A basic difference between them is that the target of classification rule mining is pre-established (namely the class), unlike to what happens in association rule mining.

Associative classification originates from the idea of integrating classification rule mining and association rule mining in order to gain advantages from both methods, arising computational performances (Liu et al., 1998). This integration is focused on the subset of AR that have classification class attribute on the right-hand-side. These special rules are also known as *class association*

rules (CARs). The first implementation of associative classification is the *Classification Based on Association* algorithm (CBA) (Liu *et al.*, 1998).

Formalism of association rules

To introduce the definitions of this section, consider a market basket analysis context. The database is a set T of transactions each of which consists of a set X of items bought in that transaction. In turn, given an object or a set of objects, it is possible to list the transactions that contain them. An item set X covers a transactions set T if this item set appears in every transaction of T . *Support count* of an item set X , denoted by $X.count$, is the number of transactions in T covered by X . It represents the frequency with which an item set X appears in a database of transactions T (Liu, 2011).

An expression of the form $X \rightarrow Y$ represents an AR, where X and Y are disjoint sets of purchasable items. A such rule states that transactions of the database T which contain X tend to contain Y , as expressed by statement of the kind “98% of customers that purchase tires and automobile accessories also get automotive service” offered by Agrawal *et al.* (1995).

In association rule mining, all rules extract will be evaluated based on their strength, selecting only a subset that satisfy predetermined conditions. *Support* and *confidence* of a rule measure its strength. The rule support express the portion of transactions containing $X \cup Y$ over the total number n of transactions of T as shown by the formula (26):

$$support = \frac{(X \cup Y).count}{n} \quad (26)$$

The confidence of a rule $X \rightarrow Y$ is the per cent of transactions of T containing X that contain also Y :

$$confidence = \frac{(X \cup Y).count}{X} \quad (27)$$

The aim of mining AR is to find all association rules in T with support and confidence greater than or equal to a threshold value pre-specified named *minimum support* (*minsup*) and *minimum confidence* (*minconf*).

In order to highlight AR among basket data it is necessary to discover item sets that occurs recurrently (Gosain and Bhugra, 2013). Classical algorithms to mine AR are *Apriori* (Agrawal and Srikant, 1994) and *FP-growth* (Han *et al.*, 2000).

CBA

The CBA algorithm consists of two parts: i) a *rule generator* (CBA-RG), based on the *Apriori* algorithm (Agrawal and Srikant, 1994) appropriately modified to mine class association rules; ii) a *classifier builder* (CBA-CB) that classifies accurately the rules previously generated. Comparing CBA with other classifier based on rules, such as C4.5 (Quinlan, 1993) and CART (Breiman *et al.*, 1984), some differences emerge. Both approaches are based on the “covering method” (Michalski, 1980), but results are different, depending on the way of application. CBA algorithm (CBA-RG module) adopts covering method, running it over all the rules mined from the entire training set. Unlike, the traditional application of covering method works on one class at a time (see also previous section on rules-based classifier), whenever removing covered examples by best rules, and learning new rules from the remaining cases. The difference among results of CBA and the other classifiers arises from the general validity of rules mined by CBA that constructs all the rules from the entire training set and then makes the best selection of rules covering training data. Furthermore, rule-pruning technique is adopted in CBA to avoid overfitting problems. Pruning represents a difference between CBA algorithm and the association rule mining. Another difference lies in the presence of CBA-CB module, being the AR not based on the classifier building.

Classification Based on Multiple Association Rules

Classification based on Multiple Association Rules or CMAR is a method following to CBA (Li *et al.*, 2001). It introduces some advances with respect to CBA. First, CMAR identifies the class label analyzing a small set of rules with high confidence instead of mine the class from a single rule. CMAR uses *FP-growth* method (Han *et al.*, 2000), a frequent pattern mining algorithm, alternative to *Apriori* method, to mine class-association rules. Then, CMAR employs a *CR-tree* data structure to store and retrieve the large amount of classification rules previously generated. *CR-tree* represents a solution to the remarkable effort handling a substantial amount of rules. Finally, pruning make the classification process more effective and efficient, by removing redundant and noisy information.

To classify a new object, CMAR compares classification rules that match the given object. The object class is simply assigned when the class label is the same for all rules matching. Otherwise, CMAR groups together rules with the same class label. Then, it evaluates the strength of each group, comparing the “combined effect” of correlation (Brin *et al.*, 1997) and support (Baralis *et al.*, 2004) of contained rules.

Classification Based on Predictive Association Rules

Classification Based on Predictive Association Rules or CPAR (Yin and Han, 2003) is a classification approach that merges the advantages of (i) associative classification and (ii) traditional rule-based classification. It adopts different strategies with respect to (i) and (ii) about the

construction of rules, for example, it generates rules directly from training data, instead of creating a large set of candidate rules, as in associative classification; moreover, it produces a more complete set of rules than traditional rule-based approaches.

CPAR originates from First Order Inductive Learner (FOIL) learning system (Quinlan, 1990; Quinlan and Cameron-Jones, 1993), modified with Predictive Rule Mining (PRM) algorithm. PRM varies the covering method (see Section Rule-Based Classification) implemented by FOIL, keeping the rules that cover positive examples and associating a “weight” to these rules. In this way, positives examples are covered by more rules, achieving higher accuracy than FOIL. Furthermore, working with large database, PRM attains greater efficiency with respect to FOIL, thanks to reducing of time consuming part in rules building. PRM reaches higher efficiency but lower accuracy than associate classification. PRM results are exceeded by CPAR, that is the evolution of PRM. It gets better the rule building process, avoiding redundant rule generation and building several rules simultaneously. Finally, CPAR evaluates the prediction power of every rule, defining its expected accuracy as the probability that an example observing the antecedent of the rule actually belongs to class predicted in the consequent. So doing, in a set of k best rules for a class, the rule with the highest expected accuracy will be chosen to class prediction.

Biographical Sketch

Alfonso Urso received the Laurea degree in electronic engineering (*Summa cum Laude*), and the PhD degree in systems engineering from the University of Palermo, Italy, in 1992 and 1997, respectively. In 1998, he was with the Department of Computer and Control Engineering, University of Palermo, as Research Associate. In 2000, he joined the High Performance Computing and Networking Institute of the Italian National Research Council (ICAR-CNR), where he is currently a Researcher in systems and computer engineering. From 2007 to 2015 he was coordinator of the research group “Intelligent Data Analysis for Bioinformatics” of the Italian National Research Council. Since January 2016 he is Head of the Palermo branch of the High Performance Computing and Networking Institute of the Italian National Research Council (ICAR-CNR). Since 2001 he has been Lecturer at the University of Palermo. His research interests are in the area of machine learning, soft computing and applications to bioinformatics. He is member of the Institute of Electrical and Electronic Engineers (IEEE), and of the Italian Bioinformatics Society (BITS).

Antonino Fiannaca received the Laurea degree in computer science engineering (*Summa cum Laude*), and the PhD degree in computer science from the University of Palermo, Italy, in 2006 and 2011, respectively. In 2006, he joined the High Performance Computing and Networking Institute of the Italian National Research Council (ICAR-CNR), where he is currently a Researcher. He is part of the Translational Bioinformatics Laboratory at ICAR-CNR. His research interests are in the area of machine learning, neural networks and bioinformatics.

Massimo La Rosa received the Laurea degree in computer science engineering (*Summa cum Laude*), and the PhD degree in computer science from the University of Palermo, Italy, in 2006 and 2011, respectively. In 2006, he joined the High Performance Computing and Networking Institute of the Italian National Research Council (ICAR-CNR), where he is currently a Researcher. He is part of the Translational Bioinformatics Laboratory at ICAR-CNR. He is member of Bioinformatics Italian Society (BITS) from 2016. His research interests are in the area of machine learning, data mining and bioinformatics.

Valentina Ravi received her Master Degree in Physics, with Biophysical address (*Summa cum Laude*), at the University of Study of Palermo, Italy. She has held post-graduate internships at the same University, where she collaborated to tutoring, teaching and dissemination activities. She has done a post-degree training in the area of interest of data mining and support decision systems at ICAR-CNR of the National Research Council, Palermo. Here she is currently involved in research activities in bioinformatics domain, with the focus on the study of data mining techniques.

Riccardo Rizzo is staff researcher at Institute for high performance computing and networking, Italian National Research Council. His research is focused mainly on machine learning methods of sequence analysis, and biomedical data analysis, and on neural networks applications. He was Visiting Professor at the University of Pittsburgh, School of Information Science, in 2001. He participates in the program committee of several international conferences and has served as editor of some Supplements of the BMC Bioinformatics journal. He is author of more than 100 scientific, 33 of them in international journals, such as "IEEE Transactions on Neural Networks", "Neural Computing and Applications", "Neural Processing Letters", "BMC Bioinformatics". He participates in many national research projects and is co-author of one international patent.

Bayes' Theorem and Naive Bayes Classifier

Daniel Berrar, Tokyo Institute of Technology, Tokyo, Japan

Introduction

Bayes' theorem is of fundamental importance for inferential statistics and many advanced machine learning models. Bayesian reasoning is a logical approach to updating the probability of hypotheses in the light of new evidence, and it therefore rightly plays a pivotal role in science (Berry, 1996). Bayesian analysis allows us to answer questions for which frequentist statistical approaches were not developed. In fact, the very idea of assigning a probability to a hypothesis is not part of the frequentist paradigm.

The goal of this article is to provide a mathematically rigorous yet concise introduction to the foundation of Bayesian statistics: *Bayes' theorem*, which underpins a simple but powerful machine learning algorithm: the *naive Bayes classifier* (Lewis, 1998). This article is self-contained; it explains all terms and notations in detail and provides illustrative examples. As a tutorial, this text should therefore be easily accessible to readers from various backgrounds. As an encyclopedic article, it provides a complete reference for bioinformaticians, machine learners, and statisticians. Readers who are already familiar with the statistical background may find the practical examples in Section "Examples" most useful. Specifically, Section "Examples" highlights some caveats and pitfalls (and how to avoid them) in building a naive Bayes classifier using R, with additional materials available at the accompanying website <http://osf.io/92mes>.

Fundamentals

Basic Notation and Concepts

A statistical experiment can be broadly defined as a process that results in one and only one of several possible outcomes. The collection of all possible outcomes is called the *sample space*, denoted by Ω . At the introductory level, we can describe events by using notation from set theory. For example, our experiment may be one roll of a fair die. The sample space is then $\Omega = \{1, 2, 3, 4, 5, 6\}$, which is also referred to as *universal set* in the terminology of set theory. A simple event is, for instance, the outcome 2, which we denote as $E_1 = \{2\}$. The probability of an event E is denoted by $P(E)$. According to the classic concept of probability, the probability of an event E is the number of outcomes that are favorable to this event, divided by the total number of possible outcomes for the experiment, $P(E) = \frac{|E|}{|\Omega|}$, where $|E|$ denotes the cardinality of the set E , i.e., the number of elements in E . In our example, the probability of rolling a 2 is $P(E_1) = \frac{|E_1|}{|\Omega|} = \frac{1}{6}$. The event "the number is even" is a compound event, denoted by $E_2 = \{2, 4, 6\}$. The cardinality of E_2 is 3, so the probability of this event is $P(E_2) = \frac{3}{6}$.

The *complement* of E is the event that E does not occur and is denoted by E^c , with $P(E) = 1 - P(E^c)$. In the example, $E_2^c = \{1, 3, 5\}$. (In the literature, the complement of an event A is also often represented by the symbol $\bar{A}$.) Furthermore, $P(A|B)$ denotes the *conditional probability* of A given B . Finally, $\emptyset$ denotes the *empty set*, i.e., $\emptyset = \{\}$.

Let A and B be two events from a sample space Ω , which is either finite with N elements or countably infinite. Let $P: \Omega \rightarrow [0, 1]$ be a probability distribution on Ω , such that $0 < P(A) < 1$ and $0 < P(B) < 1$ and, obviously, $P(\Omega) = 1$. We can represent these events in a Venn diagram (Fig. 1(a)). The *union* of the events A and B , denoted by $A \cup B$, is the event that either A or B or both occur. The *intersection* of the events A and B , denoted by $A \cap B$, is the event that both A and B occur. Finally, two events, A and B , are called *mutually exclusive* if the occurrence of one of these events rules out the possibility of occurrence of the other event. In the notation of set theory, this means that A and B are disjoint, i.e., $A \cap B = \emptyset$. Two events A and B , with $P(A) > 0$ and $P(B) > 0$, are called *independent* if the occurrence of one event does not affect the probability of occurrence of the other event, i.e., $P(A|B) = P(A)$ or $P(B|A) = P(B)$, and $P(A \cap B) = P(A) \cdot P(B)$.

Note that the *conditional probability*, $P(A|B)$, is the *joint probability* $P(A \cap B)$ divided by the *marginal probability* $P(B)$. This is a fundamental relation, which has a simple geometrical interpretation. Loosely speaking, given that we are in the ellipse B (Fig. 1(a)), what is the probability that we are also in A ? To be also in A , we have to be in the intersection $A \cap B$. Hence, the probability is equivalent to the number of elements in the intersection, $|A \cap B|$, divided by the number of elements in B ,

Fig. 1 (a) Venn diagram for sets A and B . (b) Illustration of the total probability theorem. The sample space Ω is divided into five disjoint sets A_1 to A_5 , which partly overlap with set B .

i.e., $|B|$. Formally,

$$P(A|B) = \frac{|A \cap B|}{|B|} = \frac{|A \cap B|/|\Omega|}{|B|/|\Omega|} = \frac{P(A \cap B)}{P(B)}.$$

Total Probability Theorem

Before deriving Bayes' theorem, it is useful to consider the *total probability theorem*. First, the addition rule for two events, A and B , is easily derived from Fig. 1(a):

$$P(A \cup B) = P(A) + P(B) - P(A \cap B) \quad (1)$$

We assume that the sample space can be divided into n mutually exclusive events A_i , $i = 1..n$, as shown in Fig. 1(b). Specifically,

1. $A_1 \cup A_2 \cup \dots \cup A_n = \Omega$
2. $A_i \cap A_j = \emptyset$ for $i \neq j$
3. $A_i \neq \emptyset$

From Fig. 1(b), it is obvious that B can be stated as

$$B = (B \cap A_1) \cup (B \cap A_2) \cup \dots \cup (B \cap A_n)$$

and we obtain the total probability theorem as

$$\begin{aligned} P(B) &= P(B \cap A_1) + P(B \cap A_2) + \dots + P(B \cap A_n) - \underbrace{P(B \cap A_1 \cap \dots \cap B \cap A_n)}_{= 0, \text{ because } A_i \cap A_j = \emptyset \text{ for } i \neq j} \\ &= P(B|A_1)P(A_1) + P(B|A_2)P(A_2) + \dots + P(B|A_n)P(A_n) \\ &= \sum_{i=1}^n P(B|A_i)P(A_i) \end{aligned} \quad (2)$$

which can be rewritten as

$$P(B) = P(B|A)P(A) + P(B|A^c)P(A^c) \quad (3)$$

because $A_2 \cup A_3 \cup \dots \cup A_n$ is the complement of A_1 (cf. conditions 1 and 2 above). Redefining $A := A_1$ and $A^c := A_2 \cup A_3 \cup \dots \cup A_n$ gives Eq. (3).

Bayes' Theorem

Assuming that $|A| \neq 0$ and $|B| \neq 0$, we can state the following:

$$P(A|B) = \frac{|A \cap B|}{|B|} = \frac{\frac{|A \cap B|}{|\Omega|}}{\frac{|B|}{|\Omega|}} = \frac{P(A \cap B)}{P(B)} \quad (4)$$

$$P(B|A) = \frac{|B \cap A|}{|A|} = \frac{\frac{|B \cap A|}{|\Omega|}}{\frac{|A|}{|\Omega|}} = \frac{P(A \cap B)}{P(A)} \quad (5)$$

From Eqs. (4) and (5), it is immediately obvious that

$$P(A \cap B) = P(A|B)P(B) = P(B|A)P(A) \quad (6)$$

and therefore

$$P(A|B) = \frac{P(B|A)P(A)}{P(B)} \quad (7)$$

which is the simplest (and perhaps the most memorable) formulation of Bayes' theorem.

If the sample space Ω can be divided into finitely many mutually exclusive events $A_1, A_2, \dots, A_n$, and if B is an event with $P(B) > 0$, which is a subset of the union of all A_i , then for each A_i , the generalized Bayes' formula is

$$P(A_i|B) = \frac{P(B|A_i)P(A_i)}{\sum_{j=1}^n P(B|A_j)P(A_j)} \quad (8)$$

which can be rewritten as

$$P(A|B) = \frac{P(B|A)P(A)}{P(B|A)P(A) + P(B|A^c)P(A^c)} \quad (9)$$

Both Eqs. (8) and (9) follow from Eq. (7) because of the total probability theorem (Eqs. (2) and (3))

Bayes' theorem can be used to derive the posterior probability of a hypothesis given observed data:

$$P(\text{hypothesis} | \text{data}) = \frac{P(\text{data} | \text{hypothesis})P(\text{hypothesis})}{P(\text{data})} \quad (10)$$

where $P(\text{data} \mid \text{hypothesis})$ is the *likelihood* of the data given the hypothesis ("if the hypothesis is true, then what is the probability of observing these data?"), $P(\text{hypothesis})$ is the *prior probability* of the hypothesis ("what is the *a priori* probability of the hypothesis?"), and $P(\text{data})$ is the probability of observing the data, irrespective of the specified hypothesis. The prior probability (short, *prior*) is also referred to as the (initial) *degree of belief* in the hypothesis. In other words, the prior quantifies the *a priori* plausibility of the hypothesis.

It is often assumed that the data can arise under two competing hypotheses, H_1 and H_2 , with $P(H_1) = 1 - P(H_2)$. Instead of "hypothesis", the term "model" is also frequently used. Let D denote the observed data. Then the posterior probability of the hypothesis (or model) H_1 is

$$P(H_1 \mid D) = \frac{P(D \mid H_1)P(H_1)}{P(D \mid H_1)P(H_1) + P(D \mid H_2)P(H_2)} \quad (11)$$

and the posterior probability of H_2 is

$$P(H_2 \mid D) = \frac{P(D \mid H_2)P(H_2)}{P(D \mid H_1)P(H_1) + P(D \mid H_2)P(H_2)} \quad (12)$$

From Eqs. (11) and (12), we obtain

$$\underbrace{\frac{P(H_1 \mid D)}{P(H_2 \mid D)}}_{\text{posterior odds}} = \underbrace{\frac{P(D \mid H_1)}{P(D \mid H_2)}}_{\text{Bayes factor } B_{12}} \cdot \underbrace{\frac{P(H_1)}{P(H_2)}}_{\text{prior odds}} \quad (13)$$

The *Bayes factor* is the ratio of the posterior odds of H_1 to its prior odds. The Bayes factor can be interpreted as a summary measure of the evidence that the data provide us in favor of the hypothesis H_1 against its competing hypothesis H_2 . If the prior probability of H_1 is the same as that of H_2 (i.e., $P(H_1) = P(H_2) = 0.5$), then the Bayes factor is the same as the posterior odds.

Note that in the simplest case, neither H_1 nor H_2 have any free parameters, and the Bayes factor then corresponds to the likelihood ratio (Kass and Raftery, 1995). If, however, at least one of the hypotheses (or models) has unknown parameters, then the conditional probabilities are obtained by integrating over the entire parameter space of H_i (Kass and Raftery, 1995),

$$P(D \mid H_i) = \int P(D \mid \theta_i, H_i)P(\theta_i \mid H_i)d\theta_i \quad (14)$$

where θ_i denotes the parameters under H_i .

Note that Eq. (13) shows the Bayes factor B_{12} for only two hypotheses, but of course we may consider more than just two. In that case, we can write B_{ij} to denote the Bayes factor for H_i against H_j . When only two hypotheses are considered, they are commonly referred to as *null hypothesis*, H_0 , and *alternative hypothesis*, H_1 . Jeffreys suggests grouping the values of B_{01} into grades (Jeffreys, 1961) (Table 1):

It is instructive to compare the Bayes factor with the p -value from Fisherian significance testing. In short, the p -value is defined as the probability of obtaining a result as extreme as (or more extreme than) the actually observed result, given that the null hypothesis is true. The p -value is generally considered an evidential weight against the null hypothesis: the smaller the p -value, the greater the weight against H_0 . However, the p -value can be a highly misleading measure of evidence because it overstates the evidence against H_0 (Berger and Delampady, 1987; Berrar, 2017; Berrar and Dubitzky, 2017). A Bayesian calibration of p -values is described by Sellke et al. (2001). This calibration leads to the *Bayes factor bound*, $\bar{B} = \frac{1}{-p \log p}$, where p is the p -value. Note that $\bar{B}$ is an upper bound on the Bayes factor over any reasonable choice of the prior distribution of the hypothesis " H_0 is not true", which we may refer to as "alternative hypothesis". For example, a p -value of 0.01 corresponds to an odds of, at most, about 8 to 1 in favor of " H_0 is not true". Note that the concept of "alternative hypothesis" does not exist in the Fisherian significance testing, which considers only one hypothesis, i.e., the null hypothesis H_0 . The idea of "alternative hypothesis" is firmly embedded in the Neyman-Pearsonian hypothesis testing, where the concept of the p -value does not exist. The two different schools of thought – the Fisherian and the Neyman-Pearsonian – should not be conflated; compare (Berrar, 2017).

So far, we have considered only the discrete case, i.e., when the sample space is countable. What if the variables are continuous? Let X and Y denote two continuous random variables with joint probability density function $f_{XY}(x, y)$. Let $f_{X|Y}(x \mid y)$ and $f_{Y|X}(y \mid x)$ denote their conditional probability density functions. Then

$$f_{X|Y}(x \mid y) = \frac{f_{XY}(x, y)}{f_Y(y)} \quad (15)$$

Table 1 Interpretation of Bayes factor B_{01} according to (Jeffreys, 1961)

Grade	B_{01}	Interpretation
0	$B_{01} > 1$	Null hypothesis H_0 supported
1	$1 > B_{01} > 0.32$	Evidence against H_0 , but not worth more than a bare mention
2	$0.32 > B_{01} > 0.10$	Evidence against H_0 substantial
3	$0.10 > B_{01} > 0.032$	Evidence against H_0 strong
4	$0.032 > B_{01} > 0.01$	Evidence against H_0 very strong
5	$0.01 > B_{01}$	Evidence against H_0 decisive

and

$$f_{Y|X}(y|x) = \frac{f_{XY}(x, y)}{f_X(x)} \quad (16)$$

so that Bayes' theorem for continuous variables can be stated as

$$f_{X|Y}(x|y) = \frac{f_{Y|X}(y|x)f_X(x)}{f_Y(y)} \quad (17)$$

where $f_Y(y) = \int_{-\infty}^{+\infty} f_{Y|X}(y|x)f_X(x)dx = \int_{-\infty}^{+\infty} f_{XY}(x, y)dx$ because of the total probability theorem..

In summary, Bayes' theorem provides a logical method that combines new evidence (i.e., new data, new observations) with prior probabilities of hypotheses in order to obtain posterior probabilities for these hypotheses.

Naive Bayes Classifier

We assume that a data set contains n instances (or cases) $\mathbf{x}_i$, $i = 1..n$, which consist of p attributes, i.e., $\mathbf{x}_i = (x_{i1}, x_{i2}, \dots, x_{ip})$. Each instance is assumed to belong to one (and only one) class $y \in \{y_1, y_2, \dots, y_m\}$. Most predictive models in machine learning generate a numeric score s for each instance $\mathbf{x}_i$. This score quantifies the degree of class membership of that case in class y_j . If the data set contains only positive and negative instances, $y \in \{0, 1\}$, then a predictive model can either be used as a *ranker* or as a *classifier*. The *ranker* uses the scores to order the instances from the most to the least likely to be positive. By setting a threshold t on the ranking score, $s(\mathbf{x})$, such that $\{s(\mathbf{x}) \geq t\} = 1$, the *ranker* becomes a (crisp) classifier (Berrar, 2014).

Naive Bayes learning refers to the construction of a Bayesian probabilistic model that assigns a posterior class probability to an instance: $P(Y = y_j | X = \mathbf{x}_i)$. The simple naive Bayes classifier uses these probabilities to assign an instance to a class. Applying Bayes' theorem (Eq. (7)), and simplifying the notation a little, we obtain

$$P(y_j | \mathbf{x}_i) = \frac{P(\mathbf{x}_i | y_j)P(y_j)}{P(\mathbf{x}_i)} \quad (18)$$

Note that the numerator in Eq. (18) is the joint probability of $\mathbf{x}_i$ and y_j (cf. Eq. (6)). The numerator can therefore be rewritten as follows; here, we will just use $\mathbf{x}$, omitting the index i for simplicity:

$$\begin{aligned} P(\mathbf{x} | y_j)P(y_j) &= P(\mathbf{x}, y_j) = P(x_1, x_2, \dots, x_p, y_j) \\ &= P(x_1 | x_2, x_3, \dots, x_p, y_j) P(x_2, x_3, \dots, x_p, y_j) \text{ because } P(a, b) = P(a | b)P(b) \\ &= P(x_1 | x_2, x_3, \dots, x_p, y_j) P(x_2 | x_3, x_4, \dots, x_p, y_j) P(x_3, x_4, \dots, x_p, y_j) \\ &= P(x_1 | x_2, x_3, \dots, x_p, y_j) P(x_2 | x_3, x_4, \dots, x_p, y_j) \cdots P(x_p | y_j)P(y_j) \end{aligned}$$

Let us assume that the individual x_i are independent from each other. This is a strong assumption, which is clearly violated in most practical applications and is therefore *naive* – hence the name. This assumption implies that $P(x_1 | x_2, x_3, \dots, x_p, y_j) = P(x_1 | y_j)$, for example. Thus, the joint probability of $\mathbf{x}$ and y_j is

$$\begin{aligned} P(\mathbf{x} | y_j)P(y_j) &= P(x_1 | y_j) \cdot P(x_2 | y_j) \cdots P(x_p | y_j)P(y_j) \\ &= \prod_{k=1}^p P(x_k | y_j)P(y_j) \end{aligned} \quad (19)$$

which we can plug into Eq. (18) and we obtain

$$P(y_j | \mathbf{x}) = \frac{\prod_{k=1}^p P(x_k | y_j)P(y_j)}{P(\mathbf{x})} \quad (20)$$

Note that the denominator, $P(\mathbf{x})$, does not depend on the class – for example, it is the same for class y_j and y_l . $P(\mathbf{x})$ acts as a scaling factor and ensures that the posterior probability $P(y_j | \mathbf{x})$ is properly scaled (i.e., a number between 0 and 1). When we are interested in a crisp classification rule, that is, a rule that assigns each instance to exactly one class, then we can simply calculate the value of the numerator for each class and select that class for which this value is maximal. This rule is called the *maximum posterior rule* (Eq. (21)). The resulting “winning” class is also known as the *maximum a posteriori* (MAP) class, and it is calculated as $\hat{y}$ for the instance $\mathbf{x}$ as follows:

$$\hat{y} = \underset{y_j}{\operatorname{argmax}} \prod_{k=1}^p P(x_k | y_j)P(y_j) \quad (21)$$

A model that implements Eq. (21) is called a (simple) *naive Bayes classifier*.

A crisp classification, however, is often not desirable. For example, in ranking tasks involving a positive and a negative class, we are often more interested in how well a model ranks the cases of one class in relation to the cases of the other class (Berrar and Flach, 2012). The estimated class posterior probabilities are natural ranking scores. Applying again the total probability theorem (Eq. (3)), we can rewrite Eq. (20) as

$$P(y_j | \mathbf{x}) = \frac{\prod_{k=1}^p P(x_k | y_j) P(y_j)}{\prod_{k=1}^p P(x_k | y_j) P(y_j) + \prod_{k=1}^p P(x_k | y_j^c) P(y_j^c)} \quad (22)$$

Examples

Application of Bayes' Theorem in Medical Screening

Consider a population of people in which 1% really have a disease, D . A medical screening test is applied to 1000 randomly selected persons from that population. It is known that the sensitivity of the test is 0.90, and the specificity of the test is 0.91.

- If a tested person is really sick, then what is the probability of a positive test result (i.e., the result of the test indicates that the person is sick)?
- If the test is positive, then what is the probability that the person is really sick?

The probability that a randomly selected person has the disease is given as $P(D) = 0.01$ and therefore $P(D^c) = 0.99$. These are the marginal probabilities that are known *a priori*, that is, without any knowledge of the person's test result. The sensitivity of a test is defined as $\frac{TP}{TP+FN}$, where TP denotes the number of true positive predictions and FN denotes the number of false negative predictions. Sensitivity is therefore also known as *true positive rate*; in information retrieval and data mining, it is also called *recall*. The specificity of a test is defined as $\frac{TN}{TN+FP}$, where TN denotes the number of true negative predictions and FP denotes the number of false positive predictions. Let $\oplus$ denote a positive and $\ominus$ a negative test result, respectively. The answer to (a) is therefore simple – in fact, it is already given: the conditional probability $P(\oplus | D)$ is the same as the sensitivity, since the number of persons who are really sick is the same as the number of true positive predictions (persons are sick and they are correctly identified as such by the test) plus the number of false negative predictions (persons are sick but they are not identified as such by the test). Thus, $P(\oplus | D) = \frac{TP}{TP+FN} = 0.9$.

To answer (b), we use Bayes' theorem and obtain

$$P(D | \oplus) = \frac{P(\oplus | D)P(D)}{P(\oplus | D)P(D) + P(\oplus | D^c)P(D^c)} = \frac{0.9 \cdot 0.01}{0.9 \cdot 0.01 + 0.09 \cdot 0.99} = 0.092 \quad (23)$$

The only unknown in Eq. (23) is $P(\oplus | D^c)$, which we can easily derive from the given information: if the specificity is 0.91 or 91%, then the false positive rate must be 0.09 or 9%. But the false positive rate is the same as the conditional probability of a positive result, given the absence of disease, i.e., $P(\oplus | D^c) = 0.09$.

It can be insightful to represent the given information in a confusion matrix (Table 2). Here, the number of true negatives and false positives are rounded to the nearest integer. From the table, we can readily infer the chance of disease given a positive test result as $\frac{9}{9+89}$, i.e., just a bit more than 9%.

The conditional probability $P(D | \oplus)$ is also known as *positive predictive value* in epidemiology or as *precision* in data mining and related fields. What is the implication of this probability being around 0.09? The numbers in this example refer to health statistics for breast cancer screening with mammography (Gigerenzer et al., 2008). A positive predictive value of just over 9% means that only about 1 out of every 10 women with a positive mammogram actually has breast cancer; the remaining 9 persons are falsely alarmed. Gigerenzer et al. showed that many gynecologists do not know the probability that a person has a disease given a positive test result, even when they are given appropriate health statistics framed as conditional probabilities (Gigerenzer et al., 2008). By contrast, if the information is reframed in terms of natural frequencies (as in $\frac{9}{9+89}$ in this example), then the information is often easier to understand.

Naive Bayes Classifier–Introductory Example

We illustrate naive Bayes learning using the contrived data set shown in Table 3. This example is inspired by the famous “Play Tennis” data set, which is often used to illustrate naive Bayes learning in introductory data mining textbooks (Witten and Frank, 2005). The first 14 instances refer to biological samples that belong to either the class *tumor* or the class *normal*. These samples represent the training set. Each instance is described by an expression profile of only four genes. Here, the gene expression values are discretized into either underexpressed (-1), overexpressed ($+1$), or normally expressed (0). Sample #15 represents a new biological sample. What is the likely class of this sample? Note that the particular combination of features, $\mathbf{x}_{15} = (+1, -1, +1, +1)$, does not appear in the training set.

Table 2 Confusion matrix for the example on medical screening

	D	D^c	Σ
$\oplus$	$TP = 9$	$FP = 89$	98
$\ominus$	$FN = 1$	$TN = 901$	902
Σ	10	990	1000

Using Eq. (20), we obtain

$$P(\text{tumor} | \mathbf{x}_{15}) = \frac{P(A = +1 | \text{tumor}) \cdot P(B = -1 | \text{tumor}) \cdot P(C = +1 | \text{tumor}) \cdot P(D = +1 | \text{tumor}) \cdot P(\text{tumor})}{P(\mathbf{x}_{15})}$$

Let's begin with the prior probability of "tumor", $P(\text{tumor})$. This probability can be estimated as the fraction of tumor samples in the data set, i.e., $P(\text{tumor}) = \frac{9}{14}$. What is the fraction of samples for which gene A is overexpressed (+1), given that the class is "tumor"? As an estimate for this conditional probability, $P(\text{Gene A} = +1 | \text{tumor})$, the empirical value of $\frac{2}{9}$ (cf. samples #9 and #11) will be used.

Next, to calculate $P(B = -1 | \text{tumor})$, we proceed as follows: among the nine tumor samples, for how many do we observe $B = -1$? We observe $B = -1$ for cases #5, #7, and #9, so the conditional probability is estimated as $\frac{3}{9}$. The remaining conditional probabilities are derived analogously. Thus, we obtain

$$P(\text{tumor} | \mathbf{x}_{15}) = \frac{\frac{2}{9} \cdot \frac{3}{9} \cdot \frac{3}{9} \cdot \frac{9}{14}}{P(\mathbf{x}_{15})} = \frac{0.00529}{P(\mathbf{x}_{15})}$$

$$P(\text{normal} | \mathbf{x}_{15}) = \frac{\frac{3}{5} \cdot \frac{1}{5} \cdot \frac{4}{5} \cdot \frac{3}{5} \cdot \frac{5}{14}}{P(\mathbf{x}_{15})} = \frac{0.02057}{P(\mathbf{x}_{15})}$$

With the denominator $P(\mathbf{x}_{15}) = 0.00529 + 0.02057$, we then obtain the properly scaled probabilities $P(\text{tumor} | \mathbf{x}_{15}) = 0.02046$ and $P(\text{normal} | \mathbf{x}_{15}) = 0.79554$.

Laplace Smoothing

When the number of samples is small, a problem may arise over how to correctly estimate the probability of an attribute given the class. Let us assume that at least one attribute value of the test instance, $\mathbf{x}$, is absent in all training instances of a class γ_i . For example, assume that Gene A of instance #9 and #11 in Table 3 is underexpressed (-1) instead of overexpressed (+1). Then we obtain the following conditional probabilities,

$$\begin{aligned} P(\text{Gene A} = +1 | \text{tumor}) &= \frac{0}{9} \\ P(\text{Gene A} = 0 | \text{tumor}) &= \frac{4}{9} \\ P(\text{Gene A} = -1 | \text{tumor}) &= \frac{5}{9} \end{aligned}$$

which obviously leads to $P(\text{tumor} | \mathbf{x}_{15}) = 0$. If Gene A is underexpressed (-1) in instances #9 and #11 in Table 3, then $P(\text{Gene A} = +1 | \text{tumor}) = 0$, which implies that it is impossible to observe an overexpressed Gene A in a sample of class "tumor". Is it wise to make such a strong assumption? Probably not. It might be better to allow for a small, non-zero probability. This is what *Laplace smoothing* does (Witten and Frank, 2005). In this example, we simply add 1 to each of the three numerators above and then add 3 to each of the denominators:

$$\begin{aligned} P(\text{Gene A} = +1 | \text{tumor}) &= \frac{0+1}{9+3} \\ P(\text{Gene A} = 0 | \text{tumor}) &= \frac{4+1}{9+3} \\ P(\text{Gene A} = -1 | \text{tumor}) &= \frac{5+1}{9+3} \end{aligned}$$

Table 3 Contrived gene expression data set of 15 biological samples, each described by the discrete expression level of 4 genes. A sample belongs either to class "normal" or "tumor". Instance #15 is a new, unclassified sample

Sample	Gene A	Gene B	Gene C	Gene D	Class
1	+1	+1	+1	0	normal
2	+1	+1	+1	+1	normal
3	0	+1	+1	0	tumor
4	-1	0	+1	0	tumor
5	-1	-1	0	0	tumor
6	-1	-1	0	+1	normal
7	0	-1	0	+1	tumor
8	+1	0	+1	0	normal
9	+1	-1	0	0	tumor
10	-1	0	0	0	tumor
11	+1	0	0	+1	tumor
12	0	0	+1	+1	tumor
13	0	+1	0	0	tumor
14	-1	0	+1	+1	normal
15	+1	-1	+1	+1	unknown

However, instead of adding 1, we could also add a small positive constant c weighted by p_i ,

$$\begin{aligned} P(\text{Gene A} = +1 | \text{tumor}) &= \frac{0 + cp_1}{9 + c} \\ P(\text{Gene A} = 0 | \text{tumor}) &= \frac{4 + cp_2}{9 + c} \\ P(\text{Gene A} = -1 | \text{tumor}) &= \frac{5 + cp_3}{9 + c} \end{aligned}$$

with $p_1 + p_2 + p_3 = 1$, which are the prior probabilities for the states of expression for Gene A. Although such a fully Bayesian specification is possible, in practice, it is often unclear how the priors should be estimated, and simple Laplace smoothing is often appropriate (Witten and Frank, 2005).

Mixed Variables

In contrast to many other supervised learning algorithms, the naive Bayes classifier can easily cope with mixed-variable data sets. For example, consider Table 4. Here, Gene B has numeric expression values.

Assuming that the expression values of Gene B follow a normal distribution, we can model the probability density given class y_i as

$$f(x | y_i) = \frac{1}{\sqrt{2\pi}\sigma_i} e^{-\frac{1}{2}\left(\frac{x-\mu_i}{\sigma_i}\right)^2} \quad (24)$$

where μ_i and σ_i denote the mean and standard deviation of the gene expression value for class y_i , respectively. Of course, in practice, other distributions are possible, and we need to choose the distributional model that best describes the data. In the example, we obtain $\mu_{\text{tumor}} = 21.9$, $\sigma_{\text{tumor}} = 7.7$, and $\mu_{\text{normal}} = 24.2$, $\sigma_{\text{normal}} = 8.5$. Note that the probability that a continuous random variable X takes on a particular value x is always zero for any continuous probability distribution, i.e., $P(X = x) = 0$. However, using the probability density function, we can calculate the probability that X lies in a narrow interval $[x_0 - \frac{\epsilon}{2}, x_0 + \frac{\epsilon}{2}]$ around x_0 as $\epsilon \cdot f(X = x_0)$. For the new instance $\mathbf{x}_{15}$ (Table 4), we obtain $f(12 | \text{tumor}) = 0.02267$ and $f(12 | \text{normal}) = 0.01676$, so that we can state the conditional probabilities as

$$\begin{aligned} P(\text{tumor} | \mathbf{x}_{15}) &= \frac{\frac{2}{9} \cdot 0.0227\epsilon \cdot \frac{3}{9} \cdot \frac{3}{9} \cdot \frac{9}{14}}{P(\mathbf{x}_{15})} = \frac{0.00036\epsilon}{P(\mathbf{x}_{15})} \quad \text{and} \\ P(\text{normal} | \mathbf{x}_{15}) &= \frac{\frac{3}{5} \cdot 0.01676\epsilon \cdot \frac{4}{5} \cdot \frac{3}{5} \cdot \frac{5}{14}}{P(\mathbf{x}_{15})} = \frac{0.00172\epsilon}{P(\mathbf{x}_{15})} \end{aligned}$$

The posterior probabilities are $P(\text{tumor} | \mathbf{x}_{15}) = \frac{0.00036\epsilon}{0.00036\epsilon + 0.00172\epsilon} = 0.17$ and $P(\text{normal} | \mathbf{x}_{15}) = \frac{0.00172\epsilon}{0.00036\epsilon + 0.00172\epsilon} = 0.83$. Note that ϵ cancels.

Missing Value Imputation

Missing values do not present any problem for the naive Bayes classifier. Let us assume that the new instance contains missing values (encoded as NA), for example, $\mathbf{x}_{15} = (+1, \text{NA}, +1, +1)$. The posterior probability for class y_i can then be calculated by simply omitting this attribute, i.e.,

$$\begin{aligned} P(\text{tumor} | \mathbf{x}_{15}) &= \frac{\frac{2}{9} \cdot \frac{3}{9} \cdot \frac{3}{9} \cdot \frac{9}{14}}{P(\mathbf{x}_{15})} = \frac{0.016}{P(\mathbf{x}_{15})} \quad \text{and} \\ P(\text{normal} | \mathbf{x}_{15}) &= \frac{\frac{3}{5} \cdot \frac{4}{5} \cdot \frac{3}{5} \cdot \frac{5}{14}}{P(\mathbf{x}_{15})} = \frac{0.103}{P(\mathbf{x}_{15})} \end{aligned}$$

Table 4 Contrived gene expression data set from Table 3. Here, absolute expression values are reported for Gene B

Sample	Gene A	Gene B	Gene C	Gene D	Class
1	+1	35	+1	0	normal
2	+1	30	+1	+1	normal
3	0	32	+1	0	tumor
4	-1	20	+1	0	tumor
5	-1	15	0	0	tumor
6	-1	13	0	+1	normal
7	0	11	0	+1	tumor
8	+1	22	+1	0	normal
9	+1	14	0	0	tumor
10	-1	24	0	0	tumor
11	+1	23	0	+1	tumor
12	0	25	+1	+1	tumor
13	0	33	0	0	tumor
14	-1	21	+1	+1	normal
15	+1	12	+1	+1	unknown

If the training set has missing values, then the conditional probabilities can be calculated by omitting these values. For example, suppose that the value +1 is missing for Gene A in sample #1 (Table 4). What is the probability that Gene A is overexpressed (+1), given that the sample is normal? There are five normal samples, and two of them (#2 and #8, Table 4) have an overexpressed Gene A. Therefore, the conditional probability is calculated as $P(\text{Gene A} = +1 | \text{normal}) = \frac{2}{5}$.

R Implementation

We will now illustrate how to build a naive Bayes classifier using the function `naiveBayes()` of the package `e1073` (Meyer *et al.*, 2015) in the programming language and environment R (R Core Team, 2017), which is widely used by the bioinformatics community. Here, we use the data from Table 3.

```
library(e1071)

#' Load the data.
train <- read.csv("NB_train.csv", colClasses = c('factor', 'factor', 'factor', 'factor'))
test  <- read.csv("NB_test.csv", colClasses = c('factor', 'factor', 'factor', 'factor'))

# Build the model.
NB_model <- naiveBayes(Class ~ ., data = train)

# Predict the test case.
pred <- predict(NB_model, test, type = "raw")

pred

##           normal          tumor
## [1,] 0.000202459 0.9997975
```

Surprisingly, these probabilities differ from what we calculated above, namely $P(\text{tumor} | \mathbf{x}_{15}) = 0.2046$ and $P(\text{normal} | \mathbf{x}_{15}) = 0.7954$. Why? The problem can be quite hard to spot. The reason is that the factor levels (per attribute) are not the same in the training and the test set, which causes the function `predict()` to calculate incorrect probabilities. Internally, `predict()` converts attribute values into numbers, and it does not check whether the factor levels are consistent or not.

```
str(train)

## 'data.frame': 14 obs. of 5 variables:
## $ Gene_A: Factor w/ 3 levels "0","-1","+1": 3 3 1 2 2 2 1 3 3 2 ...
## $ Gene_B: Factor w/ 3 levels "0","-1","+1": 3 3 3 1 2 2 2 1 2 1 ...
## $ Gene_C: Factor w/ 2 levels "0","+1": 2 2 2 2 1 1 1 2 1 1 ...
## $ Gene_D: Factor w/ 2 levels "0","+1": 1 2 1 1 1 2 2 1 1 1 ...
## $ Class : Factor w/ 2 levels "normal","tumor": 1 1 2 2 2 1 2 1 2 2 ...

str(test)

## 'data.frame': 1 obs. of 5 variables:
## $ Gene_A: Factor w/ 1 level "+1": 1
## $ Gene_B: Factor w/ 1 level "-1": 1
## $ Gene_C: Factor w/ 1 level "+1": 1
## $ Gene_D: Factor w/ 1 level "+1": 1
## $ Class : Factor w/ 1 level "unknown": 1
```

As we can see, the factor levels are not the same in the training and test set. The user has to ensure factor level consistency. A simple solution consists in first appending the test case to the training set and then splitting them apart. Note that the class labels also have to be consistent. At the moment, the test case has the class label "unknown", but this is not a valid label. When we add the test case to the training set, we erroneously increase the factor level of "Class", which in turn will cause `naiveBayes()` to assume that there are three classes in total.

```
train_save <- train
test_save <- test
X <- rbind(train_save, test_save)
train <- X[1:14, ]
test <- X[15, ]

# Build the model again and apply it to the test case.
NB_model <- naiveBayes(Class ~ ., data = train)
pred <- predict(NB_model, test, type = "raw")
pred

##          normal tumor unknown
## [1,]      NaN   NaN   NaN

# We have to make sure that our test case has a class label that also appears in
# the training set, so we can just choose either "normal" or "tumor".
# It does not matter which one we choose, and it has no influence
# on predict() because predict() uses only the predictor variables
test$Class <- "normal"
X <- rbind(train_save, test)
train <- X[1:14, ]
test <- X[15, ]

# Build the model again and apply it to the test case.
NB_model <- naiveBayes(Class ~ ., data = train)
pred <- predict(NB_model, test, type = "raw")
pred

##          normal      tumor
## [1,] 0.7954173 0.2045827
```

When we use `naiveBayes()`, we have to make sure that the factor levels in the training and test set are consistent. Also, we need to make sure that data types are correct. Note that the values in [Table 3](#) could be interpreted as integers, which would of course lead to different results (see the R code at <https://osf.io/gtchm/> for more details). Both pitfalls can be easily overlooked and thereby cause `naiveBayes()` and `predict()` to produce results that may look plausible but that are, in fact, incorrect.

Discussion

In this article, we derived Bayes' theorem from the fundamental concepts of probability. We then presented one member of the family of machine learning methods that are based on this theorem, the naive Bayes classifier, which is one of the oldest workhorses of machine learning.

It is well known that the misclassification error rate is minimized if each instance is classified as a member of that class for which its conditional class posterior probability is maximal ([Domingos and Pazzani, 1997](#)). Consequently, the naive Bayes

classifier is optimal (cf. Eq. (21)), in the sense that no other classifier is expected to achieve a smaller misclassification error rate, provided that the features are independent. However, this assumption is a rather strong one; clearly, in the vast majority of real-world classification problems, this assumption is violated. This is particularly true for genomic data sets with many co-expressed genes. Perhaps surprisingly, however, the naive Bayes classifier has demonstrated excellent performance even when the data set attributes are not independent (Domingos and Pazzani, 1997; Zaidi *et al.*, 2013).

Another advantage of the naive Bayes classifier is that the calculation of the conditional probabilities is highly parallelizable and amenable to distributed processing, for example, in a MapReduce environment (Villa and Rossetti, 2014). Thus, the naive Bayes classifier is also interesting for big data analytics.

The performance of the naive Bayes classifier can often be improved by eliminating highly correlated features. For example, assume that we add ten additional genes to the data set shown in Table 4, where each gene is described by expression values that are highly correlated to those of Gene B. This means that the estimated conditional probabilities will be dominated by those values, which would “swamp out” the information contained in the remaining genes.

We illustrated some caveats and pitfalls and how to avoid them when building a naive Bayes classifier in the programming language and environment R (R Core Team, 2017). Further details with fully commented code and example data are available at the accompanying website <http://osf.io/92mes>.

Closing Remarks

Harold Jeffreys, a pioneer of modern statistics, succinctly stated the importance of Bayes' theorem: “[Bayes' theorem] is to the theory of probability what Pythagoras' theorem is to geometry.” (Jeffreys, 1973, p. 31). Indeed, Bayes' theorem is of fundamental importance not only for inferential statistics, but also for machine learning, as it underpins the naive Bayes classifier. This classifier has demonstrated excellent performance compared to more sophisticated models in a range of applications, including tumor classification based on gene expression profiling (Dudoit *et al.*, 2002). The naive Bayes classifier performs remarkably well even when the underlying independence assumption is violated.

k-Nearest Neighbor (*k*-NN)

A different approach to classification or regression is possible without any model construction first. This is known as the *lazy approach* because of the working procedure: the learner does not construct any general model before seeing the test instance. The learner stores all training instances and, only when a given test instance arrives, it generalizes the information coming from the examples to classify or predict the new class label or numeric value. *k*-nearest neighbor (*k*-NN) and *case-based reasoning* are examples of lazy learner.

k-NN method is based on the nearest neighbor decision rule (Fix and Hodges, 1951, 1952; Cover and Hart, 1967), according to which the class of an object never seen before by the classifier depends on a set of previously classified records. The nearest neighbor rule is widely applied in problems of pattern recognition, text categorization, ranking models, object recognition and event recognition (Bhatia, 2010).

How it Works

k-NN compares an unknown instance with those belonging to the training set and assigns it the class according to the similarity with training instances. Consider a training set of instances as pairs (X_i, y_i) , where $X_i = (x_{i1}, x_{i2}, \dots, x_{in})$ is a tuple (i.e., a vector in the feature space representing a sequence of values concerning respectively fixed attributes) described by n attributes and y_i is the corresponding class label (qualitative or quantitative) (See the paragraphs 1 and 2 of the chapter "Data Mining: Classification and Prediction".); $i = 1, \dots, p$ is the total number of tuples in the data set. A tuple is represented by a point in a n -dimensional space of attributes (or feature space (The feature space concept was introduced in the chapter "Data Mining: Classification and Prediction", section 'Components of a Generalized Linear Model')). A new instance to be classified will take one among the class label of k training tuples that are nearest neighbors in the space of representation (see Fig. 1). By using a distance metric, the classifier establishes the neighbors in the feature space.

It is possible to use several *distances functions* to compute the similarities among tuples. This choice depends on the kind of the data set, if it includes numeric, symbolic or categorical attributes.

Distance functions

For numeric attributes, common distances are *Manhattan* and *Euclidean* distances, which represent two particular cases of the more general *Minkowski* distance.

Manhattan distance d_M between the tuples X_1 and X_2 is known also as Minkowski distance of order 1 and is given by Eq. (1)

$$d_M(X_1, X_2) = \sum_{i=1}^n |x_{1i} - x_{2i}| \quad (1)$$

The Euclidean distance d_E between two tuples X_1 and X_2 is computed as shown in Eq. (2):

$$d_E(X_1, X_2) = \sqrt{\sum_{i=1}^n (x_{1i} - x_{2i})^2} \quad (2)$$

Fig. 1 *k*-NN classification in a 2-dimensional feature space; $k=3$. The black cross represents a new instance to classify. The arrows mark the distance among the new tuple and 3 nearest neighbors.

It is known also as Minkowski distance of order 2.

Hamming distance is used to compare two tuples expressed by strings of n characters (symbolic attributes). In this case, the distance reports the total number of correspondent positions where the symbols are different. For example, considering the strings "ATCG" and "ATGG", its Hamming distance is $d_M=1$, differing only in the third position.

The computation of their distance for categorical attributes is not straightforward. The distance or, conversely, the similarity can be evaluated considering schemes of numeric "translation". Starting from the trivial case, the similarity between two categorical attributes is 1 if they are identical or 0 if they are different. Considering instances described by more than one categorical attribute, the similarity between them will increase with the number of matching attributes. This is the so-called *overlap* measure (Stanfill and Waltz, 1986). Additional sophisticated procedures allow evaluating differential grading of similarities between instances described by more than one categorical attribute (Boriah et al., 2008). Other distances can be used, for example, *Jaccard* distance (Levandowsky and Winter, 1971), *Dice's* coefficient (Dice, 1945), *Tanimoto* coefficient (Tanimoto, 1958) and *cosine* distance (Qian et al., 2004).

The k value

Once calculated the distances from the other training examples, k -NN classifier establishes the class of the new instance by choosing the most frequent label among k nearest neighbors (see Fig. 2). In prediction task, for a new instance in input, k -NN predictor returns a real value, which is the average value of k numeric labels of nearest neighbors.

The choice of the k value influences the performance of the k -NN classifier. Indeed, a too small value of k makes the classifier more sensitive to noising data. Conversely, if k value is too large, the classifier will consider also examples from other classes, possibly deviating the result of classification. In the limit case, all the training instances will be considered and the most frequent class label will be assigned to the new instance.

The good value for the number k of neighbors is experimentally determined by estimating the error rate of the classifier/predictor with a start number $k^{(0)}$. If the performance needs to be improved, the number $k^{(0)}$ is increased, according to the number of new neighbors. The error rate can be estimated through probabilistic methods (Duda et al., 1991).

k -NN Regression

For dataset of instances (X_j, y_j) described by numeric attributes as component of the vector X_j and corresponding numeric value y_j , k -NN works as a regression method. Therefore, it allows to predict the numeric value $\hat{y}$ corresponding to an unseen instance vector X , on the basis of the information of k nearest neighbors in the training set. Consider the simple case of dataset described by a single feature. Hence, the j th instance of the dataset is represented by the pair (x_j, y_j) , where x_j is a scalar. The entire dataset can be plotted in a 2-dimensional graph, where the x -axis represent the 1-dimensional feature space (see Fig. 3).

Given a new instance $(x=4; \hat{y}=?)$, k -NN provides as output a number $\hat{y}$ arising from Eq. (3) (Hastie et al., 2008):

$$\hat{y} = \frac{1}{k} \sum_{x_i \in N_k(x)} y_i \quad (3)$$

where $N_k(x)$ is the set $\{x_1, \dots, x_k\}$ of the training neighbors of the new value x . Clearly, $N_k(x)$ depends on the value chosen for k . Referring to the example depicted in Fig. 3, for $k=1$, $N_k(x)$ will contain only one instance, which is the first in the list of the nearest neighbors. Consequently $\hat{y}=y_1=6$. For $k=2$, $\hat{y}=\frac{1}{2}(6+3)=4.5$ and so on. As shown in the Fig. 3, the suitable choice of k dictates the performance (with $k=3$ the predicted value moves away from the true value).

Unlike the regression methods described below, k -NN regression is said a "non-parametric" method, since it does not assume any explicit form for the prediction function f , meaning that it does not construct a model for f .

Fig. 2 The choice of the k value conditions the output of the classifier, including more or less example of different class.

Fig. 3 k -NN regression: blue dots represent the training set plotted in a graph of y_i values against the feature values x_i . The red curve f is the true function underlying the training set. The regression method approximates the true (unknown) function. Therefore, given the new instance $x=3$, it provides as output a numeric value $\hat{y}$ (one black cross for each value of k) that should be as near as possible to the true value $f(x)$. $\hat{y}$ value changes for different values of k .

Conclusive Remarks

As resumed in the work of [Bhatia \(2010\)](#), k -NN technique includes advantages like a very fast training and a simple learning. It shows robustness to noisy training data coming from pruning noisy tuples ([Aha, 1992](#)). On the other hand, the main disadvantages concern mainly the computational complexity ([Preparata and Shamos, 1985](#)) and memory limitation of this technique. The slowness of classification can be improved by using a partial distance calculation, where only a subset of attribute is involved in the compute of the distance ([Gersho and Gray, 1992](#)). The editing of the stored tuples removes useless training examples, helping to speed up the process of classification ([Hart, 1968](#)). Furthermore, the performance of k -NN algorithm can be biased by the choice of the k value ([Guo et al., 2003](#)). Irrelevant attribute can easily mislead the decision of k -NN. For this reason, it is made more robust by a specific pruning on data tuples.

Case-Based Reasoning (CBR) Classifier

Case-based reasoning (CBR) ([Aamodt and Plaza, 1994](#); [Watson and Marir, 1994](#)), was born in response to several critical problems met by rule-based expert systems (RBES), in Artificial Intelligence field ([Schank, 1984](#)). CBR solves new problems according to a database of solved cases, namely of problem situations previously analyzed and stored. It works by comparing the characteristics of the new problem with the cases in its “historical archive” and looks for a match with stored solutions, eventually by adapting those that are similar to the examined issue ([Schank, 1982](#); [Riesbeck and Schank, 1989](#); [Kolodner, 1993](#)).

Classification is one of the possible applications of CBR in business applications, engineering and law area ([Watson and Marir, 1994](#); [Allen, 1994](#); [Rissland and Ashley, 1987](#)). In particular, CBR classifier for medical applications employs the data concerning patients’s cases and their treatments to assist in the diagnosis. First examples of applications are CASEY ([Koton, 1988](#)) heart diagnosis generator and PROTOS ([Bareiss et al., 1988](#)) for clinical audiology. There are also current applications in breast cancer domain ([Gu et al., 2017](#)).

How it Works

A crucial component of CBR is its database of information and knowledge developed with the experience that arises from previously examined situations. CBR learns from such past cases and stores them conveniently to create a *general background knowledge* database ([Aamodt and Plaza, 1994](#)). They represent the training instances of CBR, and they are employed to solve a new problem, called *new case*.

The solutions stored in the knowledge-base or *case-base* can be directly applied to the new problem or eventually adapted. Indeed, CBR can modify a retrieved solution for a new, different problem. Furthermore, it is able to enrich its case-base with each new solved case. Each solved case can be kept as single experience or grouped with others similar in order to form a generalized case. The problem-solving approach of CBR can be resumed in the following a cycle schema.

CBR cycle

CBR follows a cyclic process to solve a problem, learning from experience and reusing it to treat a new case.

A CBR cycle can be described by the four steps:

1. RETRIEVAL
2. REUSE
3. REVISION
4. RETAINMENT

First, CBR searches for a possible match of the new case with training instances and returns the solution eventually found (*retrieval*). Such solution will be reused for the new examined case (*reuse*). If the perfect match is not retrieved, CBR looks for neighbors, which are stored instances similar for a subset of attributes to the new case. Then, it proposes an answer by combining the solutions of neighbors (*revision*). Finally, CBR includes the new solved case in the case-base, incrementing its experience (*retainment*). The Fig. 4 depicts the schema of operation of a case-based reasoning. The following sub-sections shortly describe the steps of a CBR cycle.

Retrieval

The retrieval of cases consists of a set of subtasks such as:

- identification of features
- matching
- selection.

The identification of features is focused to detect the relevant characteristic of the new problem, to treat it comparing with the case-base. The matching task searches for a solution for the new problem recurring to the case-base. If any exact match is found, it provides a set of stored cases similar for features to the new instance, referring to a given similarity threshold. Selection step chooses the best match among the similar cases.

Reuse

The reuse procedure involves two fundamental steps: first, identifying the differences between the two cases and then establishing what part of the retrieved case can be used in the new case.

Fig. 4 Cycle of CBR.

Revision

In case revision step, CBR follows two procedures: first, it evaluates the solution provided from reuse step by applying that in the environment of the new problem; if the reuse solution is successful CBR retain it, otherwise CBR repair the solution, detecting errors and elaborating a new solution. In the repair step, the system recurs to a specific domain knowledge.

Retention

The retention step corresponds to the learning for CBR. It is focused on the ability to select the information to retain if a new solution is proposed; it is also important to establish how to encode the retained information, and consequently the indexing of the new entry in case-base for the future retrieval.

Operating Details

The CBR performance is conditioned by the content of its case-base and by its structure. Indeed, the effectiveness and the efficiency of CBR strongly depend on the search case and matching process. Hence, the structure of case-base, also called *case memory*, should be suitably organized and indexed, as a vocabulary to favor the retrieval and reuse. Consequently, the representation of cases is crucial for CBR, to describe the case content appropriately, by involving their features. A further challenge consists into integrating case-base structure to create a general domain knowledge model.

Two examples of case memory models are “Dynamic memory model” (Schank, 1982) on which it is based the first case-based system called CYRUS (Kolodner, 1983) and “Category & exemplar Model” (Porter and Bareiss, 1986), described by Aamodt and Plaza (1994).

Conclusive Remarks

CBR classifier performance depends on the choice of the similarity metric, which is involved in the identification of neighbors, and on the choice of suitable methods to combine solution. It is fundamental select remarkable features for indexing training cases.

Incrementing the number of the stored cases, the reasoner increases its abilities and accuracy. Conversely, beyond a given limit, the rising of computational time to find relevant cases determines a reduction of efficiency. In this case, an expedient is editing the database, discarding those cases redundant or useless.

Genetic Algorithms Classifier

Genetic algorithms (GAs) (Holland, 1975) are stochastic algorithms used to solve optimization and search problems, (see Michalewicz, 1992). They are a type of evolutionary computation techniques (Rechenberg, 1973) inspired by adaptation principles of natural selection. They are domain independent methods, therefore, GAs are applied in several fields of computer science, for example as optimization process in a number of problems such as routing and scheduling (the traveling salesman problem), game-playing, cognitive modeling, transportation problem and control problems (Janikow, 1993; Goldberg, 1989; DeJong, 1985) and also in the field of Neural Networks (Royas, 1996).

Vocabulary

GAs works on a set of possible solutions to a given problem, by applying stochastic methods that simulate natural ways of evolution. Biological world influences both computing methods and language of GAs. In biological language, the genetic information of each individual is contained in *chromosomes* (see Fig. 5, left side). A chromosome consists of units or *genes* that control hereditariness of characters. Each gene occupies a given position or *locus* on the chromosome. The same gene can be in several states or *alleles*, entailing the different ways in which an individual's character (for example eyes color) manifests itself.

In GAs, the chromosomes represent candidate solutions to a given problem. A chromosome is made up of a sequence of genes (see Fig. 5, right side). The genes encode a particular characteristic or feature of the candidate solution. For example, considering a problem of optimization, the optimization function is a chromosome. Each parameter of the optimization function is a gene, encoded by either a single bit or a short block of bits. A gene represented by single bit can be in two states, either “0” or “1”. These two possibilities are the alleles of that gene. The different alleles of the same gene represent different values of the same feature in GA vocabulary. For a gene that encodes more than two possible alleles, a block of bits is used.

How it Works

The basic idea of GA is to find the best individual in a population of chromosomes, namely candidates solutions of a given task (optimization function or classification rule), following a process of natural selection. During such process, the fitter individuals of the population are chosen to create the *offspring*. The offspring will result in a new successive population replacing the previous

Fig. 5 (left) Biological representation of a chromosome: a string of genes (bands with letters), which are a portion of DNA. Each portion occupies a given locus on the chromosome. Uppercase or lowercase letter in a locus represents the allele of the same gene; (right) Computational representation of a chromosome: a sequence of genes, which are codified by one or more bits. The possibilities “0” or “1” at the same locus give rise to alleles of the same gene.

one. Each replacement gives rise to a new *generation*, potentially including the fittest one among several individuals and hence the best solution to the problem.

GAs employ the way of natural selection to allow proliferation and modification of good solutions and inhibit bad solutions, in perfect analogy with the biological environment (Chang and Lippmann, 1991).

The implementation of GA is based on its *genetic operators*. The simplest form of GA employs *creation*, *selection*, *crossover* and *mutation*. Genetic operators will be discussed in the following section. Furthermore, an *evaluate function* (Michalewicz, 1992) or *fitness function* (Mitchell, 1996) allows to evaluate each individual by assigning it a score, namely the *fitness*. The fitness of an individual depends on its goodness as a solution for the considered problem. The candidate who approaches the best solution will have the highest score. The following section introduces an example of the fitness function and a simple scheme of GA with genetic operators.

Fitness function

In the optimization problem, the aim is to find the set of parameters that maximize or minimize a given function. Consider for example the function of Eq. (4) (Riolo, 1992):

$$f(x) = x + |\sin(32x)|, \quad \text{with } 0 \leq x \leq \pi \quad (4)$$

The value of x that maximize the function are the candidate solutions. The possible values of x are encoded in strings of bit: they represent the chromosomes on which will operate the GA. To evaluate a candidate bit string, it is enough to convert it in the correspondent real number x' and calculate the value of the function in x' . This value is the fitness of the string.

Operators of GA: Creation, selection, crossover, mutation

The evolution process in GAs starts with the *creation* of the initial population by the specific homonym genetic operator. The individuals in a population are chromosomes encoded by the bit string that is initialized to “1” or “0” values.

Once the first population is created, the fitness of individuals is evaluated. Then, the *selection* operator identifies the fittest candidates to breed. The probability of selection is indeed an increasing function of fitness (Mitchell, 1996). The same chromosome can be selected more times to reproduce, if it is fitter than others.

A *crossover* operator acts on a couple of selected chromosomes, the *parents*, exchanging portions of these. In Fig. 6, it is shown the simplest crossover operator, which acts in a single locus of the chromosome (single point). First, the crossover operator randomly chooses a locus on the parents’ chromosomes. Then it exchanges the substrings, creating two offspring. The aim of this process is to mix the useful parts of both parents to produce the new better chromosomes.

Crossover can provide new chromosomes until that the individuals are not too similar to each other. For this scope, the new individual can be altered by the operator *mutation* that randomly selects bits in a string and then inverts them, as shown in Fig. 6.

Fig. 6 The parents “blue” and “pink” strings breed through the crossover operator. It creates two new chromosomes children (offspring) from the single crossover point at the fourth-bit position. The mutation operator changes the offspring.

Table 1 Pseudocode summarizing the steps of a generic GA

1. Creation of a random population of n chromosomes (initialization of bit strings);
2. Evaluation of the fitness of each chromosome;
3. Intermediate step (to repeat until creating n offspring):
 - a) Selection of two chromosomes as parents (based on step 2)
 - b) Crossover with probability p_c
 - b) Mutation with probability p_m
4. Replacement of the current population with new population;
5. Go to step 2.

Crossover and mutation are random operators, meaning that they will act with a fixed probability, respectively p_c (crossover probability or crossover rate) and p_m (mutation probability or mutation rate).

A simple scheme of operation of GA is illustrated below.

Scheme of a simple GA

The process begins with the creation operator, which produces an initial population of chromosomes. The intermediate step provides a recursive modification of population, by applying other genetic operators such as selection, crossover and mutation. At the end of the evolution process, only the fittest offspring will survive, representing the selection of the best solutions.

The following scheme shown in [Table 1](#) summarizes the steps of a GA observing what has been reported by [Mitchell \(1996\)](#):

The iterations of this procedure are called *generations*. Their number varies typically from 50 to 500 or more ([Mitchell, 1996](#)). The set of generations is called *run*. After a run, the fitness function will indicate one or more individuals highly fit in the population. The performance of the GA often depends on the characteristic chosen to treat a given problem, for example, the size n of population and p_c and p_m value. Considering the importance of randomness in GA, a better information can results from the average over many different runs of the given problem.

Optimization Problems and Classification Tasks

In optimization problems, the individuals in a population are the possible solutions ([Sivanandam and Deepa, 2007](#)). Fitness function assesses each solution by a fitness value ([Chang and Lippmann, 1991](#)).

Genetic search algorithms show a suitable approach to feature creation, feature and examples selection. These skills make GAs suitable for pattern classification task ([Chang and Lippmann, 1991](#)).

In classification problems, the individuals in the initial population are rules randomly generated. Classification accuracy evaluates the fitness of a rule, considering a set of training instances ([Han et al., 2012](#)).

Conclusive Remarks

The main advantages of GAs are robustness and independence of their search mechanism from the application field. In particular, domain independence allows that a new employee needs only a proper encoding of the given problem ([Janikow, 1993](#)). In speech

recognition domain, GAs have a processing time for features selection similar than traditional methods but use a lower number of input feature (Chang and Lippmann, 1991). GAs can work on tasks of artificial machine-vision producing outputs of classification with error rate nearly 0%, obtaining results better than KNN and Neural Network Classifiers (Chang and Lippmann, 1991). The ease of application is also an advantage of GAs, in addition to the effectiveness in finding a proper solution to in-depth search problem (Chang and Lippmann, 1991).

On the other hand, run time of GAs can be long (Chang and Lippmann, 1991; Janikow, 1993), being this one of major drawbacks of this technique. Furthermore, domain independence entails as a disadvantage that the performance of GAs is heavily dependent on the quality of the problem coding.

Linear and Nonlinear Regression Prediction

The aim of this section and the successive one is to introduce numerical prediction methods (See also the first two paragraphs of the “Data Mining: Classification and Prediction” article.), which answers to given task by supplying continuous target values. Problems that require numerical predictors can be addressed by a *function estimator* or *regressor* (Flach, 2012). It provides real numeric values starting from a set of numeric input data such as observations or measurements. This kind of predictor builds a *model function* that fits training data of a given task. Such a function will be able to predict unknown numerical data for a new instance pertaining to the same domain of the learned problem (Han et al., 2012).

Regression predictors forecast data trends by applying the statistical tool of regression analysis in several domains of interest from marketing management (Stock and Watson, 2003) to bioinformatics analysis (Wu et al., 2009).

Regression is an approach mostly used for numerical prediction. According to the kind of the problem to treat, two different models can be used, linear and nonlinear regression. Both models describe a relationship between a dependent variable y and one or more independent variables X . The main difference between these two type of regression relies on the relationship between the independent variable and the parameters of regression, i.e., if it is a linear combination of those or not.

The curve obtained from regression analysis is straight-line for linear regression and can be of other types for nonlinear regression (polynomial curves with a degree greater than 1 are considered a special case of multiple regression and can be treated with linear regression; they are an example of functions called linear regression models) (Flach, 2012; Bishop, 2006).

How Regression Prediction Methods Work?

Regression prediction methods fall into the category of *geometric models*. Here, the techniques represent a given task and therefore data set in an n -dimensional geometric space (Introduced in section “Linear and nonlinear classifier” of the “Data Mining: Classification and Prediction” article.), called feature space, being each instance described by n features. Regression methods construct classification models by employing geometric concepts such as lines or planes or considering measures of distance as similarities among properties.

To train a regression prediction method, it is necessary to model training data with a function f . Training data are a set of examples, where each instance is described by a pair (X, y) , $X = (x_1, \dots, x_n)$ is the vector of the features and y is the predefined numeric label representing a “true” function value. Starting from the training data set, a function f that maps an input vector of attributes X from the feature space to the space of real number will be built, providing $f(X)$ as output. The input X is the vector of the independent or predictor variables, whereas $f(X)$ is the dependent or *response variable* (Flach, 2012).

During the training process, the predictor learns the best function that fits the data, identifying the suitable parameters $w = (w_1, \dots, w_n)$ for f . The learning relies on the difference or *residual* (ϵ_i) between the actual and the predicted values, for the i -th instance respectively y_i and $f_w(X_i)$, as shown in Eq. (5)

$$\epsilon_i = y_i - f_w(X_i) \quad (5)$$

In particular, to avoid that positive and negative errors mutually cancel out, it is usual to consider squares of residuals (ϵ_i)² to evaluate regression models. Therefore, the *error function* (The error function was introduced in the chapter “Data Mining: Classification and Prediction”.) is expressed from the *residual sum-of-squares* $RSS(w)$, given by $\sum_{i=1}^p \epsilon_i^2$, as shown in the following formula (6):

$$RSS(w) = \sum_{i=1}^p (y_i - f_w(X_i))^2 \quad (6)$$

where the sum run over the total number p of instances in training set.

The *method of the least squares* is used to find the best function, minimizing the error function RSS with respect to the parameters w . The function f_w looks for this procedure will be bound to satisfy the relation of minimum squares of residuals, and it will be hence as close to the data as possible.

Linear Regression Predictor

Linear is the simplest type of regression. The model is a linear function of a predictor variable X . When a scalar predictor variable is used rather than a vector, the independent variable X is a single number x . In this basic case, known as *simple linear regression*, it is hypothesized that the model function describing each instance i of the data is straight-line, expressed by Eq. (7).

$$f_w(x_i) = w_0 + w_1 x_i \quad (7)$$

where the weights w_0 and w_1 are respectively the intercept and the slope of the line, also known as *regression coefficients* or *regression parameters*. To get the coefficients that are suitable for the given problem, $RSS(w)$ will be minimized. Indeed, according to the least squares method, the weights values will be obtained by solving the system of two *normal Eqs. (8) and (9)* which put equal to zero the partial derivatives of RSS with respect to the parameters weights w_0 and w_1 :

$$\frac{\partial RSS}{\partial w_0} = -2 \sum_i^p (y_i - w_0 - w_1 x_i) = 0 \quad (8)$$

$$\frac{\partial RSS}{\partial w_1} = -2 \sum_i^p (y_i - w_0 - w_1 x_i) x_i = 0 \quad (9)$$

The system leads to the solutions shown in Eqs. (10) and (11):

$$w_1 = \frac{\sum_{i=1}^p (x_i - \bar{x})(y_i - \bar{y})}{\sum_{i=1}^p (x_i - \bar{x})^2} \quad (10)$$

and

$$w_0 = \bar{y} - w_1 \bar{x} \quad (11)$$

where $(x_i; y_i)$ is one of the p pairs of data set, and $\bar{x}$ and $\bar{y}$ are the mean value of the set $\{x_i\}$ and $\{y_i\}$ where $i = 1, 2, \dots, p$.

In training phase, the predictor finds the weights w_1 and w_0 and therefore the builds the function f that models the data set. Linear regression predictor will employ this function to make a numerical prediction about a new numeric instance x' as input in Eq. (7).

Multiple linear regression

When the independent variable is a vector $X = (x_1, \dots, x_n)$, Eq. (7) changes in Eq. (12):

$$f_w(X) = w_0 + \sum_{j=1}^n w_j x_j \quad (12)$$

where the vector of weights w expresses the regression coefficients (or parameters). Now, the curve that fits the data change from a straight-line to a plane (for $n=2$) or a more general hyperplane (for $n>2$). Each component of the vector X is a predictor variable, and hence the regression is defined *multiple* instead of *simple*, see previously, where a single scalar predictor variable x is used. Even in this case, the residual sum-of-squares $RSS(w)$, expressed by Eq. (6) has to be minimized with respect to the parameters w to obtain their best values, according to the minimal squares method.

Polynomial regression

Polynomial regression adopts the function $f_w(x)$, defined in Eq. (13):

$$f_w(x) = w_0 + w_1 x + w_2 x^2 + \dots + w_m x^m = \sum_{j=1}^m w_j x^j \quad (13)$$

where m is the order of the polynomial and x is the only predictor variable. Although the polynomial curve is a nonlinear function of the independent variable x , it is a linear combination of the polynomial coefficients w . Such kind of functions can be treated as linear regression. Indeed, linear regression is used for models that are linear in the parameters (are in the predictor variables linear or not).

The least squares method can be applied to estimate the parameters, resorting to the technique of multiple regression. Indeed, it is possible to consider a set of new variables as expressed in Eq. (14):

$$x^j = x_j \quad (14)$$

where $j = 1, \dots, m$. Replacing these new variables in Eq. (13), each term of order higher than one is substituted with a new independent variable and the polynomial function takes the form of Eq. (12), resulting in a linear form of the multiple predictor variables.

Nonlinear Regression

Nonlinear regression is employed to describe observational data by using a function $f_w(X)$ that is a nonlinear combination of the model parameters. In such function, the independent variables can be greater or equal to one. An example of nonlinear regression

curve is in the following Eq. (15):

$$f_w(X) = w_0 x_1^{w_1} x_2^{w_2} \quad (15)$$

where $w = (w_0, w_1, w_2)$ is the vector of the parameters and $X = (x_1, x_2)$ is the vector of independent variables.

For nonlinear regression, there is not a general method to obtain the best parameters. Indeed, the least squares method for nonlinear case leads to a system of normal equations without an analytic solution for w . Therefore, numerical methods will be considered to solving nonlinear least squares.

In general, nonlinear regression entails an iterative procedure to estimate the best fit. A first fitting curve is generated from an initial value for each parameter. The RSS function, see Eq. (6), estimates the vertical distance between the data points and this curve. The next step tries to reduce such distance adjusting regression parameters iteratively, leading to a minimum of RSS. The obtained parameters depend on the choice of the initial values and also on the numerical optimization methods adopted to minimize RSS.

Examples of numerical methods used to minimize RSS are:

- (i) the gradient descent (or steepest descent) method;
- (ii) the Gauss-Newton method;
- (iii) the Levenberg-Marquardt method.

Gradient descent (or steepest descent) method

This technique (It was introduced in the “Data Mining: Classification and Prediction” article, about the backpropagation algorithm of feedforward neural networks.) exploits the information of the gradient of a function to find, step by step, the direction of steepest descent to its minimum value. The method begins with an initial arbitrary solution of the minimization problem and then changes it with a variation in the direction indicated by the gradient.

In the regression case, RSS is the function to minimize by varying the parameters w . The method starts generating a first fitting curve resulting from an initial value $w^{(0)}$ for the parameters. Then, it calculates the RSS between the actual value y_i of data set and the value resulting from the first fitting curve $f_{w^{(0)}}(x_i)$. To minimize this RSS value, the initial solution $w^{(0)}$ will be updated iteratively considering the relation $w^{(k+1)} = w^{(k)} + \alpha_k p_k$, where k is the step of procedure iteration, α_k is the small amount of variation for the parameter w , and $p_k = -\nabla \text{RSS}(w^{(k)})$ is the direction of steepest descent. RSS is computed at every new step, to monitor the procedure. The minimum will be reached when every further variation of w will produce an increase in the corresponding RSS value.

Gauss-Newton method

As for the previous method, Gauss-Newton starts from an initial estimate for the parameters $w^{(0)}$. In the next step, it approximates the fitting function f as a function of the parameter w with a Taylor-series about the point $w^{(0)}$. At the 1st order, the fitting function is approximated to a line, according to the local linear model. Hence, RSS' is computed considering the linear approximation of f and minimized following the usual linear squares methods. The resulting value for the parameters $w^{(1)}$, is used in the next iteration of the method, until the entire procedure converges, i.e., when the original RSS is minimized (Ruckstuhl, 2010).

Levenberg-marquardt

It consists of a blending of the previous methods, taking respective advantages. Indeed, the gradient descent works well in the initial iterations, but its performance decreases when parameters are near to the best values. On the other hand, Gauss-Newton method works better in successive iterations rather than in early ones. Levenberg-Marquardt starts its process by using a gradient descent approach and gradually changes it with the Gauss-Newton approach (Motulsky and Christopoulos, 2004).

Further considerations

Unlike the linear case, nonlinear regression can find a local minimum of the RSS curve that is not the “true” best values for the regression parameters. An example of a false minimum is shown in Fig. 7. Finding a local minimum does not depend on the numerical method chosen, since it can be determined by the initial choice of the parameters $w^{(0)}$. To overcome this problem, it is advisable to repeat nonlinear regression many times with different parameters, i.e. using different initial values. The optimization process can guarantee the best fit solution if different choice of the vector $w^{(0)}$ for the regression curve lead to the same minimum in RSS curve.

Goodness of a Model

Once the model is built, it can be useful to confirm the goodness of the fit. The meaning of the data, when it is known, suggests the type of regression to use and, as a general rule, the goodness of a fit relies on the acceptability of the parameters’ value found. In general, to confirm the goodness of a fit, it is used the r^2 or R^2 index (traditionally distinct for linear and nonlinear regression respectively) and the residual analysis.

Fig. 7 Finding a local minimum is an intrinsic problem of nonlinear regression. It can be overcome by running nonlinear regression using different initial values for several computations.

Fig. 8 Two cases of comparison between the fitting curve and the horizontal line passing through the mean value $\bar{y}$ of y_i data (B and D). Above: a case of linear regression (A); Below: a case of nonlinear regression (C).

r^2 or R^2

r^2 index is a number without units between 0.0 and 1.0. It is calculated through Eq. (16):

$$r^2 = 1.0 - \frac{RSS_{\text{reg}}}{RSS_{\text{tot}}} \quad (16)$$

where RSS_{reg} is the same of Eq. (6) and RSS_{tot} indicate the residual sum-of-squares of actual data point y_i from a horizontal line of equation $y = \bar{y}$, i.e., passing through the mean of all y_i values. r^2 , therefore, states if the found function of regression fits the data better than a horizontal line, in which case the r^2 value is close to 1. The comparison is shown in Fig. 8:

R^2 have the same meaning of r^2 but is capitalized to indicate nonlinear case.

Residual analysis

The residual analysis allows assessing if the model chosen to describe the data is suitable or not. This analysis evaluates the trend of residuals ϵ_i of Eq. (5) as a function of the independent variables X . The Fig. 9 illustrates three plots of residuals ϵ_i against the single independent variable x . A random pattern in the plot (left panel) confirms that a linear model is suitable for the regression analysis. Otherwise, another model would be used.

Fig. 9 Two typical patterns for residual plot: ϵ on the y-axis vs a single independent variable x . (a) the random plot suggest that the linear fitting model is a good choice to describe the data; (b) a non-random plot suggests a nonlinear model.

Conclusive Remarks

Method of regression rely on the assumption that the scatter of the data around the fitting line or curve follows a Gaussian or normal distribution. Therefore, the error of the dependent variable is random with mean zero. Furthermore, another hypothesis is that the variance of the error is a constant (*homoscedasticity*), i.e. the measure of the square variability of the error with respect to the mean of its distribution is uniform along the curve (Motulsky and Christopoulos, 2004). Therefore, there should not be any dependence of residuals from fitted values (otherwise, the method of *weighted* least squares has to be used; it will be discussed in Section “Estimating Parameters: Least Squares Estimation”).

Finally, the linear regression described above represents an appropriate prediction method when the dependent variable is a continuous variable (namely, it follows a Gaussian distribution). A generalization of linear regression can be made including non-continuous data for the dependent variable, and will be treated in Section “Generalized Linear Models”.

Generalized Linear Models

The regression analysis is a statistical method used to estimate the possible relationship between two types of variables. According to the regression method, a dependent variable Y or response variable (here, the response variable is indicated with uppercase to highlight that is a random variable) is expressed as a function of one or more independent variables, also known as *predictor* or *explanatory variables* of the form $X=(x_1, \dots, x_n)$. Generalized Linear Model (GLM) (Nelder and Wedderburn, 1972) is a generalization of the linear regression. It allows to model categorical response variables as a function of explanatory variables by using linear regression.

Categorical response variables or observations can be binary, having “yes” or “no” possibilities as outcomes or more generally, “success” or “failure”. To describe such binary observations of the response variable Y , it is usual to assume a binomial distribution for the data set y_i .

If the observations are counts, then a Poisson or negative binomial distribution is suitable to describe such data that will be nonnegative integers (Agresti, 1996).

Common types of GLMs are logistic regression and Poisson regression, which are employed respectively for the previous two cases. They will be described in the following sections.

Components of a Generalized Linear Model

A generalized linear model is composed of three components: i) random component, ii) systematic component, iii) link function. The *random component* specifies the response or dependent variable Y and the probability distribution hypothesized for it. The *systematic component* points out the explanatory or independent variables $(x_1, \dots, x_n)$, which describe each instance X_i of the data set, where $i=1, \dots, p$ is the total number of instances in the data set. Values of the explanatory variables are treated as fixed and not as random variable. The *link function* $g(\mu)$ indicates a function of mean μ of the probability distribution of Y , being $\mu=E(Y)$ the expected value or mean of Y . The expected value μ of a probability distribution can change depending on the explanatory variables. For example, the probability of the incidence of a disease can be considered as function of the presence of a risk factor. GLMs uses a *prediction equation* or *model equation* to relate this expected value or mean to the explanatory variables through the link function. Such model equation has a linear form, as shown in Eq. (17):

$$g(\mu) = \alpha + \beta_1 x_1 + \dots + \beta_n x_n \quad (17)$$

where the linear combination of the explanatory variables is known as *linear predictor*. α and β_j are the coefficient of regression, with $j=1, \dots, n$ if the independent variables are n .

The simplest link function is the *identity link* $g(\mu) = \mu$. If put in the left side of Eq. (17), it describe a linear model for the mean response as a function of the independent variables. Using only one explanatory variable, the model equation with identity link has the form shown in Eq. (18):

$$\mu(x) = \alpha + \beta x \quad (18)$$

This is known as ordinary linear regression model (the model Eq. (18) with regression coefficients α and β recalls Eq. (7) of the linear regression method with regression coefficients respectively to w_0 and w_1), employed for continuous responses. Therefore, linear regression is a special case of GLMs, known as *Normal GLM* because it assume a normal distribution for Y .

Other link functions consider a nonlinear relation between μ and the predictor variables. An example is the *log link function*, which considers the log of the mean $g(\mu) = \log(\mu)$. Prediction Eq. (17) employs log link function as left side when the mean μ can not be negative, as with count data. GLM using the log link function is known as the *loglinear model*.

Another nonlinear link function is the *logit link*: $g(\mu) = \log\left(\frac{\mu}{1-\mu}\right)$, which models the log of an odds. It is convenient when $0 \leq \mu \leq 1$, as a probability. GLM using the logit link function is known as *logit model* or *logistic regression model*.

The next sections aim to describe GLMs for discrete responses in the two most important case: logistic regression models for binary data and loglinear models for count data.

Logistic Regression

Logistic regression (Cox, 1958) is the most common method for analysis of binary response data (Dobson, 2001). The logit model estimates the probability of a binary response Y (random component) as a function of one or more predictor or independent variables $\{x_j\}$ (systematic component), where $j=1, \dots, n$. For simplicity, it will be introduced the case of a single explanatory variable x .

The possible outcome for a response variable Y is denoted by 1 ("success") or 0 ("failure").

The distribution of the response variable Y is specified by the probabilities $P(Y=1) = \pi$ or $P(Y=0) = 1 - \pi$ for the single observation. The number y of successes in n independent observations follows the binomial distribution with index n and parameter π , as shown in Eq. (19):

$$P(y; \pi) = \binom{n}{y} \pi^y (1 - \pi)^{n-y} \quad (19)$$

where $y=1, 2, \dots, n$. The binomial distribution expected value (the expected value $E(Y)$ is the probability-weighted average of all possible outcomes of a random variable) or mean $E(Y) = \mu = n\pi$ and variance (the variance $\text{var}(Y) = \sigma^2 = E(Y - E(Y))^2$ is the expected value of the squared difference between a random variable and its mean) $\text{var}(Y) = \sigma^2 = n\pi(1 - \pi)$.

Binomial data are described by a GLM having the prediction Eq. (20):

$$g(\pi(x)) = \log\left(\frac{\pi(x)}{1 - \pi(x)}\right) = \alpha + \beta x \quad (20)$$

where $\log\left(\frac{\pi(x)}{1 - \pi(x)}\right)$ is the *logit function* of π , also known as "logit(π)". Logit function is the link function between the mean probability π and the linear regression expression. From Eq. (20) it is possible to obtain the relationship between the success probability $\pi(x)$ and the predictor variable x . It is nonlinear, but varies continuously following a characteristic S-shaped curve, described by the so-called *logistic regression function* of Eq. (21):

$$\pi(x) = \frac{1}{1 + e^{-(\alpha + \beta x)}} \quad (21)$$

where x is the single independent or explanatory variable, α and β are the coefficients of regression. The β value establish the rate of sigmoid variation. As shown in Fig. 10, the increase or decrease of the curve depends on the positives or negative value of β . The rate of change of the sigmoid becomes steeper for greater values of $|\beta|$. For $\beta=0$ the binary response Y is independent of the explanatory variable x and the sigmoid becomes a horizontal line.

The outcomes of π are number between 0 and 1. They can be considered as the probability that the dependent variable Y is a success case or not (i.e., if the class label of Y is "yes" or "no" respectively).

Logistic regression classifier

Logistic regression can be used also to solve problems of classification. In general, logistic regression classifier can use a linear combination of more than one feature value or explanatory variable as argument of the sigmoid function. The corresponding output of the sigmoid function is a number between 0 and 1. The middle value is considered as threshold to establish what belong to the class 1 and to the class 0. In particular, an input producing an outcome greater than 0.5 is considered belong to the class 1. Conversely, if the output is less than 0.5, then the corresponding input is classified as belonging to 0 class (Harrington, 2012).

Fig. 10 Logistic regression functions, increasing and decreasing curve respectively for positives and negatives values of the β parameter. The second panel shows two different rate of change for two different positive value of β .

Nominal and ordinal logistic regression

Binomial or binary logistic regression is specific to treat a response variable with binary or binomial categories, as “true” or “false”, “male” or “female”, “healthy” or “sick” etc. Cases where the response variable considers more than two categories are described by nominal or ordinal logistic regression (Dobson, 2001), depending on whether they belong to ordered categories or not. An example of ordinal variable is one that can assume the values “low”, “medium” or “high” as the level of response to a medical treatment. It is an ordinal variables because follow ordered scales, unlike the nominal variables, for example “classical”, “rock”, “blues” or “jazz” as favorite type of music. Methods used for nominal variables can be used for ordinal ones. Conversely it is not true (Agresti, 1996).

Poisson Regression

Poisson regression is the GLM used to describe frequencies or count data. Such data usually exhibit a Poisson distribution for the probability to count a number y of events in a given temporal interval, knowing the average number θ of events in that interval. Poisson distribution is shown in Eq. (22):

$$P(y; \theta) = e^{-\theta} \frac{\theta^y}{y!} \quad (22)$$

where $y=0,1,2,\dots$. The only parameter of the distribution is θ and it can take positive values ($\theta > 0$); it expresses the mean and also the variance of the probability distribution, i.e., respectively $E(Y)=\theta$ and $var(Y)=\sigma^2=\theta$. This means that the variability of the counts tends to increase when the number of counts increases.

The link function for this GLM is the log link function. Therefore, the prediction equation follows the loglinear model shown in Eq. (23):

$$g(\theta) = \log(\theta) = \alpha + \beta x \quad (23)$$

The mean θ is an exponential function of the explanatory variable x , as shown in Eq. (24):

$$\theta(x) = \exp(\alpha + \beta x) = e^\alpha (e^\beta)^x \quad (24)$$

The values of the parameter β determine how the mean θ varies with the explanatory variable, increasing or decreasing respectively for positives or negatives β . If $\beta=0$ the means of Y is independent of x .

How GLMs Work

Estimating parameters: Maximum likelihood estimation

For a continuous random response variable Y , the probability density function or probability distribution is denoted as $P(y; \phi)$, where y is the observation of the Y variable for a fixed ϕ , which is the vector of parameters of the distribution, with components like the expected value $E(Y)$ and variance $var(Y)$. In general, the parameters values are unknown. Data sample allows to estimate these parameters by using the so-called *likelihood function*. The likelihood function $L(\phi; y)$ has the same algebraic form of the probability density function but conversely, L is a function of ϕ , for y fixed. The method of estimation of the parameter is based on the *Maximum Likelihood (ML) estimation*, which finds the parameter value that maximizes the likelihood function. The value of ϕ which maximizes the likelihood function is called *maximum likelihood estimate of ϕ* , and is indicated as $\hat{\phi}$. Frequently, it can be convenient to deal with the *log-likelihood function* $l(\phi; y) = \log L(\phi; y)$. Indeed, the parameter value sought $\hat{\phi}$ will maximize also the log-likelihood function. It will be found by differentiating the $L(\phi; y)$ or $l(\phi; y)$ with respect to each ϕ_j , and solving the simultaneous equations $\frac{\partial L(\phi; y)}{\partial \phi_j} = 0$ for $j=1,\dots,p$. In practical applications, numerical methods allow find $\hat{\phi}$ without solve these equations. GLMs works with such numerical approximations.

Fig. 11 Binomial likelihood functions for a number of success $y=0$ and $y=5$ successes in $n=10$ trials. Likelihood function says that the probability of $y=0$ for the head outcome in $n=10$ throws has a maximum for $\hat{\pi}=0$ (unfair coin).

Example of application

Considering the binomial case, whose probability distribution is expressed by Eq. (19), likelihood function says how the probability of a given number of successes y in n trials varies as a function of the success parameter π of the single trial. It is expressed by $L(\pi; y)$, where $0 \leq \pi \leq 1$ for binomial distribution. For example, the success parameter for the heads output ($Y=1$) in a single throw of a fair coin is $\pi=0.5$. The Fig. 11 shows the likelihood function for two fixed numbers of success $y=0$ and $y=5$ in $n=10$ throws. (The number of success could be considered as the head outcome in the coin throw). The likelihood function for $y=0$ has the form $L(\pi; 0) = \binom{10}{0} \pi^0 (1-\pi)^{10} = (1-\pi)^{10}$. For binomial outcomes of y successes in n trials, the likelihood function has a maximum for $\hat{\pi} = y/n$.

Estimating parameters: Least squares estimation

Another method of estimate for the parameter of a model is that of least squares, already introduced in the previous Section “Linear Regression Predictor” (linear and nonlinear regression). Here, considering Y_i independent random variable with $i=1, \dots, p$ and indicating with μ_i their respective expected values, the hypothesis is that each μ_i is a function of a regression parameters vector β . The estimator $\hat{\beta}$ is that minimizes RSS, namely the sum of squares of the differences between observed Y_i and expected values $\mu_i(\beta)$: $RSS = \sum [Y_i - \mu_i(\beta)]^2$ (as seen above in Eq. (6)). $\hat{\beta}$ is the parameter for which the RSS is minimized. Therefore, as seen in Eqs. (8) and (9), it is obtained by solving simultaneous equations of the type: $\frac{\partial RSS(\beta)}{\partial \beta_j} = 0$, where $j=1, \dots, n$.

If the variance σ_i^2 is not the same for each Y_i , then the weighted sum $RSS = \sum \frac{1}{\sigma_i^2} [Y_i - \mu_i(\beta)]^2$ is minimized, ensuring that the Y_i observations with greater variance, that mean less reliable, have a less effect on the estimates. This is the *weighted least squares method*.

Also for the least squares method, it is possible to resort to numerical approach to find the estimator.

Under assumption of Gaussian distribution for the value of Y , least squares estimates coincide with the ML estimates (Agresti, 1996).

Fitting generalized linear models

Newton-Raphson algorithm

In GLMs, a numerical algorithm is used to find ML estimates as distribution parameters values $\hat{\phi}$ of the model (as a function of regression coefficients $\hat{\beta}$). It starts assuming an initial value for the parameters maximizing the likelihood function. Through successive approximations, the parameters values tend to get closer to the ML estimates. For binomial logistic regression model and Poisson loglinear regression model, the above-mentioned method is the *Newton-Raphson algorithm* (Agresti, 1996). This algorithm is a simplification of the Fisher scoring algorithm. Through the Newton-Raphson algorithm, the log-likelihood function is approximated by a second – degree polynomial curve in the neighborhood of the initial parameter guess. Indeed, for a such parabola-shaped function it is easier to determine the value corresponding to the maximum. This value will be the second guess for the ML estimate. Hence, the algorithm iterates the approximation with the concave parabola in the neighborhood of this second guess. This procedure is repeated until the location of the maximum does not change anymore.

Model checking

It is possible to evaluate the goodness of a fit considering the distance between the observed value y_i and the fitted values $\hat{\mu}_i$, namely the residuals $y_i - \hat{\mu}_i$, for each observation i of the dataset.

To check a model involving a Normal distribution (Normal GLM), it is usual to consider a *standardized residual* obtained by dividing it by the estimate $\hat{\sigma}$ of its unknown σ parameter (the standard error $\sigma = \sqrt{\text{var}(Y)}$), namely the root square of the

variance), as shown in Eq. (25):

$$r_i = y_i - \hat{\mu}_i / \hat{\sigma} \quad (25)$$

If the assumption at the base of the model is correct, then the residuals should follow a Normal distribution with mean of zero and constant variance. They should be also independent from the explanatory variables. The goodness of the choice of the model adopted to describe the data is checked using suitable graphical methods. For example, a plot of residual against each explanatory variable should not show any pattern (as illustrate in Fig. 9). In addition, a plot of residuals against the fitted values $\hat{\mu}_i$ allows to detect an eventual change in variance, in violation of the assumption of constant variance (homoscedasticity) (as discussed in Section “Conclusive Remarks”) (under Linear and nonlinear Regression Prediction). Further, to examine the goodness of the model, the residuals can be aggregated and, as already seen above (Section “How Regression Prediction Methods Work”) it is preferable to consider the sum of the squares of residuals on the entire dataset: $\sum (y_i - \hat{\mu}_i)^2$.

A quantitative test to check the goodness of a fitting model is the χ^2 in the following Eq. (26):

$$\chi^2 = \sum \frac{(O_i - E_i)^2}{E_i} \quad (26)$$

where the argument of the sum is the square of the standardized residuals of Eq. (25). In particular, Eq. (26) becomes Eq. (27) for the logistic model and Eq. (28) for the Poisson:

$$\sum r^2 = \sum \frac{(y_i - n\hat{\pi}_i)^2}{n\hat{\pi}_i(1 - \hat{\pi}_i)} \quad (27)$$

$$\sum r^2 = \sum \frac{(y_i - \hat{\theta}_i)^2}{\hat{\theta}_i} \quad (28)$$

where the sum run over the total number of data considered.

The χ^2 test evaluates the agreement between the observed distribution of data and the expected GLM employed to describe the data. It provides a numeric value that allows establishing if the supposed GLM describes adequately the data.

Conclusive Remarks

GLMs represent a unifying model of several statistical methods. They are a generalization of the linear regression (Section “Linear Regression Predictor”) because include response variables that follow a distribution model different from the Gaussian model (therefore not necessarily continuous but also categorical response variable) (Agresti, 1996; Dobson, 2001).
